Reflex heat, on the other hand, is of great value.<sup>12</sup> The application of warm pads, short-wave currents, diathermy and so forth to various portions of the body not involved results in a tendency toward reflex vasodilatation of the major vessels and their collaterals distally. It has definite advantages and, so far as we know, is without danger. Wilkins, Doupe and Newman<sup>13</sup> have shown that the increase in blood flow resulting from local heat is not so great as that produced by warming the body.

## Typhoid Vaccine

The intravenous use of typhoid vaccine has been proved to be of great value in the treatment of thromboangiitis obliterans, although we do not recommend its use in cases of arteriosclerosis obliterans. Specially prepared typhoid vaccine should be used. The H antigen prepared by Eli Lilly and Company and recommended by Barker<sup>14</sup> is satisfactory. For some years, we have used typhoid vaccine prepared by the Kirk Biological Laboratories, of Bloomfield, New Jersey. For this purpose, it is diluted to a strength of 100,000,000 organisms per cubic centimeter. It is given intravenously, and the first dose should not exceed 5,000,000 organisms. The object is to produce a fever of 2 or 3°F., *without a chill*. When the repeated dose fails to produce an adequate response, the amount should be increased by 3,000,000 to 5,000,000 organisms. This should be given every three or four days, and a careful temperature chart should be kept.

Administration of this vaccine is continued until the ulceration or gangrene is healed, and for several months thereafter for the purpose of developing adequate collateral vessels. In our experience, the use of typhoid vaccine produces a more rapid response both in release from pain and in healing than the intravenous use of hypertonic saline, citrate or similar solutions.

## Vasodilating Drugs

In general, the use of the vasodilating drugs has been rather disappointing in the treatment of occlusive vascular disease. They may be roughly divided as follows: the nitrites and allied compounds; theobromine, Theocalcine and allied compounds; the choline compounds<sup>15</sup>; and papaverine. Although each of these products has specific indications and values in other fields, in the treatment of these two major vascular diseases, they are of rather doubtful merit. For example, in studies published several years ago,<sup>16</sup> it was shown that reflex heat was much more reliable and effective than papaverine.

## Tissue Extracts

The therapeutic use of various tissue extracts has been studied in our laboratory for ten years. We have employed various extracts prepared from the heart, skeletal muscles, liver and pancreas. Of these, the pancreatic tissue extracts have seemed the most effective in the treatment of intermittent claudication in man. Details of these studies have been reported elsewhere.<sup>17</sup> In brief, however, it is our opinion that the present, relatively pure form

of pancreatic extract (Depropanex) does favorably affect intermittent claudication. Ergometric studies that demonstrate this fact rather clearly have been made.<sup>17</sup> Patients have been enabled to walk longer distances after changing from previous therapy through the single addition of pancreatic tissue extract. More than 200 patients with this syndrome have been studied, slightly over 60 per cent showing a marked improvement and another 15 per cent showing moderate improvement—marked improvement was taken to mean an increase in walking ability whereby a patient who could walk only two or three blocks was finally able to walk ten blocks or more. This, we believe, enables him to carry on most types of occupation in a conservative manner.

This material is injected in doses of 3 cc. intragluteally two or three times a week. It has been established that pancreatic extract is nontoxic when given intravenously, although it is not used by this route in the treatment of intermittent claudication. The exact mechanisms of its action are not very well understood. It is an epinephrine antagonist in rabbits, but has not been shown to have marked vasodilating properties in man. The most popular theory at present is that it acts as a replacement product, supplying a greater concentration in the blood of substances that are essential to correct muscle metabolism but have been reaching the muscle tissue in reduced amounts because of the narrowing of the total vascular bed. Early studies of the effects of pancreatic extracts on the development of atherosclerosis in rabbits fed on cholesterol appeared to indicate that they retarded the deposition of cholesterol in the wall of the aorta. Further studies with additional series of rabbits have, however, failed to confirm this observation.<sup>18</sup> Further fractionation of this substance is now being attempted in the hope of isolating an active principle.

#### *Mechanical Therapy*

Mechanical therapy in various forms has become the vogue rather recently. One of the first of these machines to receive general attention was that known as the pressure-suction boot. Although this principle was used in the treatment of the circulation before 1800, it remained for Landis and Gibbon<sup>19</sup> and Hermann and Reid<sup>20</sup> to perfect mechanized units for this purpose. Since the apparatus has had much widespread publicity and general use, it is not necessary for me to go into the details of the technic. As in most new forms of therapy, the experimental claims were overoptimistic. It was at various times stated to be of value in the treatment of arterio-

sclerosis, thromboangiitis obliterans, Raynaud's syndrome, acute embolism, frostbite and almost every form of circulatory impairment that comes to mind. Actual experience with this apparatus has markedly reduced the indications for its use. At present, it may be said to be of value in the treatment of frostbite, acute embolism (if a well-trained surgical and medical team is not available for the surgical removal of the embolus) and a few selected cases of arteriosclerosis obliterans in which the lesion is small and not infected and the level of blockage is below the level at which the cuff is applied. On the other hand, the following contraindications have been definitely established: the presence of thrombophlebitis—this excludes many cases of thromboangiitis obliterans, since these patients tend to develop thrombophlebitis very easily; the presence of infection in the lesion; and lesions whose level is higher than that at which the cuff can be applied.

#### *Reactive Hyperemia and Intermittent Venous Occlusion*

The use of intermittent venous occlusion has been advocated from several sources. Most of this work is based on the original studies of Lewis and Grant,<sup>21</sup> in which reactive hyperemia, both arterial and venous, was described. We have conscientiously used this apparatus on 23 cases at the New York Post-Graduate Medical School and Hospital. Favorable reports have been published by Collens and Wilensky,<sup>22</sup> de Takats, Hick and Coulter,<sup>23</sup> and Wilson and Ogston.<sup>24</sup> Unfavorable results have been published by Veal and McCord<sup>25</sup> and Allen and McKechnie,<sup>26</sup> and we<sup>27</sup> have also reported unfavorably on the use of this equipment. The reactive hyperemia that undoubtedly occurs is, as pointed out by Roy and Brown<sup>28</sup> and Lewis and Grant,<sup>21</sup> in the final analysis an attempt on the part of the tissues deprived of a proper blood supply to become repossessed of it, and the phenomenon of reactive hyperemia is related in its degree to one factor, namely, the blood-flow debt, which is usually a product of the amount by which flow is reduced and the time over which the reduction has been maintained. We question very strongly the advisability of subjecting these already malnourished tissues to additional periods of deprivation of adequate blood supply to increase the blood flow thereafter, especially when the amount of the blood flow is roughly equal to that developed during the preceding phase of the cycle. We have, therefore, discontinued the use of this form of therapy in our clinic, although—as in all types of treatment—there

are reports of patients who apparently improved while this therapy was being carried on.

### *Vasoscillating Bed*

The third form of mechanical therapy that has been receiving widespread attention is that known as the vasoscillating bed, which was first described by Sanders.<sup>29</sup> By means of this bed, the head and feet of the patient are alternately elevated and lowered, a complete cycle taking from one to three minutes. This is another form of Buerger's exercises, the great difference being that this type may be continued for twenty-four hours a day if necessary, whereas Buerger's exercises can be maintained only for twenty minutes once or twice a day. We do not find it necessary to use this or any other elaborate mechanism in the treatment of thromboangiitis obliterans, but in the treatment of arteriosclerosis obliterans with impending or actual gangrene or ulceration we have found this to be of great value. More than 150 cases have now been studied at our hospital. Although it is difficult in all forms of therapy to evaluate the results satisfactorily, we have become increasingly convinced of its merit. Our experience conforms with the results recently published from the Mayo Clinic<sup>30</sup> and the Vascular Clinic of the Northwestern Medical School.<sup>31</sup> Healing of ulcerations that had previously been extremely obstinate and a general improvement in circulation in many cases have been noted. The progress is relatively slow, and it is frequently necessary to keep the patient on the bed steadily for at least a month. After this time, the patient may be allowed to be up and about during the day, but it is imperative for him to have eight hours' treatment at night on the bed. This is continued over a period of months or even years, and it appears to be of real value in increasing the ability of the collateral vessels to take over the burden of the functions associated with tissue nutrition. We usually employ a thermostatically controlled light as part of the equipment with the bed.

\* \* \*

Of all types of experimental or clinical research, none presents more difficulties than the correct evaluation of therapeutic agents. Many published studies are valueless because the author has neglected to consider other factors that he introduced into the picture simultaneously with the form of treatment that he was attempting to evaluate. Other studies are open to grave question because both known and unknown factors that affect the results were unavoidably present.

A proper estimation of the worth of a new treatment, therefore, rests on its use only in the presence of adequate controls and freedom from extraneous factors that may be influencing the clinical course of the patient. For example, forms of therapy have been reported as being of great value in the treatment of peripheral vascular diseases when they have been employed at the same time that the patient was put at complete rest, made to abstain from smoking, given soaks and wet dressings and allowed to take alcohol by mouth. Any or all of these factors are capable of markedly influencing the therapeutic response. In addition, the factor of seasonal variation is frequently neglected. Vascular diseases (with the exception of erythromelalgia) usually tend to respond favorably to warm weather, so that if, for example, cases of Raynaud's syndrome or thromboangiitis obliterans are treated, the factor of environmental temperature trend may play a role in the picture.

Failure to consider these factors has frequently necessitated a complete revision of the original conceptions of the value of a therapeutic agent. This paper has been presented with careful consideration of this aspect of the problem, but I should like to emphasize the fact that even under these conditions it is highly probable that further re-evaluation will take place during the next ten years.

## A POSTOPERATIVE FOLLOW-UP STUDY OF FOUR HUNDRED AND SIXTY-NINE THYROID PATIENTS

ARTHUR M. GREENE, M.D.,<sup>1</sup> AND LEWIS M. HURNTHAL, M.D.<sup>2</sup>

BOSTON

IN 1934, a follow-up study of 303 thyroid patients was reported from this clinic.<sup>1</sup> Those cases had been observed after subtotal thyroid

which operation was performed from January, 1932, to January, 1937.

The definition of the term "thyrocardiac" given in the previous report is as follows: a patient with hyperthyroidism who has persistent auricular fibrillation or flutter up to the time of operation, or congestive heart failure with or without regular heart rhythm or both. Data concerning associated findings are given in Table 1.

It is not the purpose of this report to discuss in detail the pathologic physiology of the heart in hyperthyroidism. A review of this subject has recently been made from this clinic.<sup>2</sup> We wish to point out again, however, the fundamental difference between congestive heart failure due to hyperthyroidism on the one hand and congestive heart failure from intrinsic heart disease on the other. The heart fails in the former because of its inability to maintain circulatory needs for increased bodily metabolism, and in the latter because it cannot maintain circulatory needs for a normal bodily metabolism. The superimposition of auricular fibrillation in either group greatly adds to the heart's inefficiency. These relations are diagrammatically presented in Figure 1

### FIRST GROUP (1922-1932)

The majority of these patients were seen in the clinic during the five-year period following operation. Thereafter, contact was made mostly by questionnaires, which were frequently completed by the patient's physician. In 1932, the final out-

ectomy over a period of one to ten years. Excellent results and a low operative mortality were demonstrated. The present report concerns a further follow-up study of the same group, and in addition, the present state of 166 cases in

<sup>1</sup>From the Department of Internal Medicine, Lohrey Clinic, Boston

<sup>2</sup>Formerly fellow in medicine, Lohrey Clinic

<sup>3</sup>Director, Department of Medicine, Lohrey Clinic

come was determined in 84 per cent, whereas in 1938 and 1939, 83 per cent were followed (Table 2).

Mortality

In 1934, the case mortality following operation was reported as 4.3 per cent.<sup>1</sup> Since that time, 13

formed elsewhere before the patients came under our observation. Thus, the probable operative mortality is about 3 per cent.

Sufficient time has not yet elapsed, nor has the number of cases been large enough, to permit the construction of accurate tables of life expectancy. However, a presentation of certain facts demon-

FIGURE 1. Relation of Circulation Rate to Metabolic Rate in Various Types of Thyroid Disease and Hypometabolism.

The data are based on clinical observations of circulation times (arm-to-mouth method, with decholin) and basal metabolic rates. The thyrocardiac patient with congestive failure is represented in the fourth column, with elevated basal metabolic rate and normal circulation time; this should be compared with the findings for the patient with ordinary congestive failure (second column).

of this group of patients have been reoperated on, with 2 deaths, the total mortality following operation being 5.0 per cent.

TABLE 2. Follow-Up Data on Patients in the First Group.

Number of patients living, with auricular fibrillation. . .	56 (27%)	42 (25%)
Subsequent reoperation because of recurrent hyperthyroidism and congestive failure (2 operative deaths) . . . . .		2

\*One to ten years.  
†Six to sixteen years.

A little more than five hundred operative procedures were carried out on these 303 patients, including an estimated nineteen operations per-

strates the outcome to the present time. If the number of years that the patients were expected to live are totaled, the average for those who died after having survived operation is seventeen years. Actually, these patients lived only an average of six years; only 1 patient lived out his life expectancy. Of the total now living, only 6 have lived beyond their expected term of life, and the rest have still not reached their predicted span of life. Figure 2 shows the average expectancy of each year group up to and including 1928, and the number of years actually lived to date. These fall short of life expectancy, and it is doubtful if the group living at present will make up the discrepancy.

Figure 3 shows the present status of these patients. The numbers now alive, dead and untraced are easily seen. Since 1926, the majority are still living, but before that time the majority were dead. It probably may be assumed that the same proportion of those alive and dead exists among the untraced patients. Figure 4 shows what is known about patients who could not be

traced at this time. It depicts the number of patients lost track of during any year following operation and the number of patients followed for twelve or more years until last heard from, and also the number who lived for various intervals following operation.

#### *Persistent or Recurrent Hyperthyroidism*

Up to the time of this follow-up, hyperthyroidism recurred in 27 cases at various intervals

FIGURE 2. *The Average Expectancy in Years and Average Years Lived by Thyrocardiac Patients.*

*The number of years lived to date is shown in the cross-hatched areas, and falls short, by half, of the natural expectancy. The small number of cases in each group does not permit accurate conclusions, but the trend is distinctly abnormal.*

following operation. It is not always possible to decide whether a patient has persistent or recurrent hyperthyroidism, but of these, 6 might be said to have had persistent hyperthyroidism; the remainder had recurrent hyperthyroidism. Recurrence developed as long as ten years after operation. Of the 14 who were reoperated on, 3 died postoperatively (1 included in the former mortality figures), and 10 have so far remained well, or were well until they died; in 1, the disease has persisted and the patient is still taking Lugol's solution. Five patients were given x-ray treatment; 4 are still well, and 1 has not been

traced. Six patients were well controlled on Lugol's solution; 4 were not, and they were given roentgen-ray treatment as mentioned above. Of the total group, 6 are dead, 3 untraced, and 6 alive.

To determine the percentage of recurrent or persistent hyperthyroidism following subtotal thyroidectomy is at best a difficult problem. Many factors are involved, such as adequate or inadequate surgery, the length of time followed, the accuracy of the initial diagnosis, the type of goiter and the method of computing the percentage. To say that a certain number of patients have recurrences within a five-year period does not mean that the chance of recurrence is ended. Considered from the point of view of the whole life history of these patients, the final estimate of recurrence cannot be made until that history is complete.

Of the 303 patients operated on in this group, 41 have had to have secondary operations or other methods of controlling hyperthyroidism up to the present time. Nineteen of the 41 were operated on before they were first seen in the clinic. It is true that some of these patients may have had inadequate surgery, especially since the operations were done between 1917 and 1925; nevertheless, they must be included.

If these 19 cases, as well as the postoperative deaths and 51 untraced cases, are excluded, there remains a total of 221 cases from which the percentage of recurrences can be computed. Hyperthyroidism developed in 22, making a percentage of 10. In the 221 cases, 71 patients have died since operation. Of those dead, 4 were known to have hyperthyroidism (2 postoperatively); there is thus a known recurrence in 18 of 154 living patients, or 12 per cent for this particular group of patients with hyperthyroidism. The final percentage of recurrence cannot be accurately foretold, therefore, until these 154 patients have all died, which may require another ten years or more of observation.

This experience with recurrent or persistent hyperthyroidism, along with consideration of the 19 patients who had been operated on before coming under our care and who fell into the thyrocardiac group because of either insufficient surgery or a persistent or recurrent hyperthyroidism, illustrates that serious consequences may occur if patients are allowed to drift along with what seems to be mild hyperthyroidism. If the disease is mild, some may be controlled with iodine, but they must be followed carefully and operated on again if necessary. It seems probable that 2 patients who died postoperatively from recurrent hy-

perthyroidism could have been saved had they submitted to operation before severe heart failure and moderately severe hyperthyroidism developed. The degree of hyperthyroidism does not always foretell whether fibrillation or heart failure will subsequently develop. The diminished cardiac reserve in many of these cases, because of degenerative or other types of heart disease, cannot withstand at times even the burden of mild degrees of thyroid overactivity without loss of compensation.

*Auricular Fibrillation*

In the original group, there were 262 cases of fibrillation. Quinidine was used in 64 cases and was successful in restoring normal heart rhythm in 52. At the 1932 follow-up, there existed 56 cases of persistent auricular fibrillation. At the

and in the other spontaneously after the withdrawal of thyroid. The presence of auricular fibrillation after operation did not appear to shorten life as judged by the fact that 27 per cent of the patients alive in 1932 and 25 per cent of those alive in 1938 had auricular fibrillation. Most of these patients are taking daily rations of digitalis.

Recurrence of congestive heart failure is rare in the absence of coexistent organic heart disease, such as mitral stenosis. It developed a second time in 4 cases, owing to recurrence of hyperthyroidism.

*Causes of Subsequent Deaths*

Twelve patients were said to have died of heart disease; 11 died from either cerebral hemorrhage

FIGURE 3. *The Number of Living, Dead and Untraced Patients in Each Year Group.*

present writing, 42 cases probably exist. In 5 cases in which the heart rhythm had been restored to normal, auricular fibrillation again developed without a known recurrence of hyperthyroidism, whereas 4 other patients returned with auricular fibrillation caused by recurrence of hyperthyroidism. Recurrence of auricular fibrillation took place in 2 cases with the administration of thyroid for mild postoperative myxedema, but normal rhythm was quickly restored—in one by the use of quinidine

or embolus when auricular fibrillation was present. It is difficult to assign the cause of these deaths accurately, but embolus seems the likeliest possibility. One patient died of mesenteric embolism. Four died of cancer, and in many the cause was not determined.

*Present Condition of Health*

An attempt to grade results is at best difficult and is not entirely satisfactory. Infirmities of age

and the presence of some unrelated disease, along with our inability to examine a good many of the patients personally, are some of the reasons why an accurate statement regarding results at the time of follow up is impossible.

In 111 cases, the rhythm is regular, and the patients are in good health, in 33, auricular fibrillation is present, but the patients are otherwise in

### Mortality

The case mortality in this group was 47 per cent. For the two groups, a total of 469 cases, the case mortality from operation is 4.5 per cent.

Fifty four one stage operations, 94 two stage operations, and 17 three stage procedures (two hemithyroidectomies and a pole ligation) were carried out, this makes a total of 293 operative

FIGURE 4 Data on Survival of Traced and Untraced Patients  
Although the number of patients operated on in 1922, 1923 and 1924 was relatively small  
the trend drops sharply after eleven years

good health, and in 20, the patients are in poor health from diverse causes, either auricular fibrillation or regular rhythm being present.

### SECOND GROUP (1932-1937)

The recent group of 171 thyrocardiac cases (1932-1937) is summarized in Table 3. One fact stands out in comparison to the first group, namely, that the number of cases of congestive heart failure seems to have decreased in relation to the number of cases of established auricular fibrillation. A little more than a third in this group had definite congestive failure as compared with more than half of those reported in the first group. The probable explanation is that these cases are being recognized or that the patients are being advised to have operation earlier than formerly.

procedures and thus gives an operative mortality of 27 per cent.

### Persistent or Recurrent Hyperthyroidism

Four of the 166 patients operated on had had a previous thyroidectomy. In 5 of these cases, hyperthyroidism recurred, 3 patients were reoperated on, and 2 are taking Lugol's solution. The incidence of recurrence to date in these cases is low, but sufficient time has not elapsed to permit a comparison with the first group.

### Auricular Fibrillation

Twenty four per cent of those traced and alive still have auricular fibrillation, as compared with 25 per cent in the first group. Quinidine sulfate was used in 33 cases, and in 20, normal rhythm developed during its administration. In some cases

in which quinidine fails to restore normal rhythm shortly after operation, a spontaneous return to normal may occur at a later date. Four such

cases were noted in this group. On the other hand, in our earlier experience, normal rhythm

perthyroidism or myxedema occurring at three months. As can be seen, the largest number of cases before operation had a metabolic rate between +30 and +40 per cent, and after operation a rate of between +10 and -10 per cent.

SUMMARY

Four hundred and sixty-nine thyrocardiac cases in which operation was performed from 1922 to 1937 have been followed. In the first group of 303 patients operated on between 1922 and 1932, 164, or 54.1 per cent, are living; 122 have normal heart rhythm, and 42 continue to have auricular fibrillation. Of the second group of 166 operated cases, 128 patients are still living, 98 of whom have normal heart rhythm.

The case mortality was 4.5 per cent, and the operative mortality was slightly less than 3.0 per cent.

The incidence of recurrent hyperthyroidism in

FIGURE 5. *Basal Metabolic Rates before and Three Months after Operation.*

was not infrequently restored in patients who had persisted in having auricular fibrillation two and three years after operation.

In this group, 1 case of hemiplegia followed the use of quinidine and restoration of normal rhythm, whereas 3 cases of embolism (1 pulmonary and 2 cerebral) followed operation on patients who had not been treated with quinidine.

Basal Metabolism

A comparison of the basal metabolic rates before and three months after operation is given in Figure 5. These include all cases of persistent hy-

perthyroidism or myxedema occurring at three months. As can be seen, the largest number of cases before operation had a metabolic rate between +30 and +40 per cent, and after operation a rate of between +10 and -10 per cent.

Although these patients are restored to normal activity for the most part, their expectancy of life based on the present follow-up falls considerably short of the predicted expectancy.

## POLLEN DISEASE IN THE ABSENCE OF POSITIVE SKIN TESTS\*

ABRAHAM COLMES, MD†

BOSTON

THERE is a small but distinct group of patients who, with the advent of the spring, summer or fall, suffer from characteristic bronchial, nasal or ocular symptoms, reminiscent of pollen disease, but who on skin testing fail to react to any of the prevailing pollens and molds.<sup>1,2</sup>

That these symptoms are due to some atmospheric inhalant, most probably pollens, is suggested by the fact that they recur each year, during a well defined pollen period, and cease when this period is over. In addition, the intensity of the symptoms varies directly with the extent of pollen pollution in the air.

In further support of this hypothesis is the fact that when patients in this group are placed in air filtered rooms, or when they change residence to a new locality with a different pollen flora, they are relieved. Most important, however, is the observation that these patients respond satisfactorily to specific pollen therapy, and in some cases even systemic reactions occur in the course of treatment. Such therapeutic results and the concomitant systemic reactions are possible only when patients are specifically sensitive to the substances injected.

What these patients lack to fulfill the criteria of pollen disease is positive skin tests. In some cases this lack seems only relative, since suggestive endermal reactions may be obtained with pollen extracts in high concentration, high potency extracts, however, often produce false positives, thus minimizing the value of the tests. In others, the more delicate ophthalmic<sup>3</sup> or nasal<sup>4</sup> tests, performed with dry, unaltered pollens, may give a clue to the correct diagnosis. But even these tests bear no constant relation to the symptoms. The only rational approach to this problem seems to be the history of the case, backed by a knowledge of the prevailing atmospheric flora during the respective seasons of the year, and a proper appraisal of the presenting symptoms.

The presenting symptoms in this group merit particular mention. In patients with bronchial complaints, wheezing may be absent or slight, the chief difficulty being either a harassing cough or complete apnea. Many patients become refractory to adrenalin and fall into a state of complete physical exhaustion bordering on collapse.

Those suffering from nasal symptoms complain more of stuffiness than of sneezing, and their chief difficulties are constant blowing of the nose and a sense of suffocation, particularly at night. The so called "ocular" group suffer from severe itch, altogether out of proportion to the local conjunctivitis. In general, severity characterizes the symptomatology in this group.

The incidence of negative skin tests to pollen has been variously estimated at between 2<sup>1</sup> and 13 per cent<sup>2</sup> of the total cases of hay fever.

During the last few years, I have observed 28 such patients, or about 7 per cent of the total pollen cases treated. Eleven of these, or 39 per cent, suffered from asthma, and a similar number from hay fever. Three, or 11 per cent, had cough as the chief complaint, and 3 others had conjunctivitis.

An evaluation of the clinical characteristics of allergy in this group reveals an incidence of positive family history, past history of allergy and

TABLE 1 Findings in 28 Allergic Patients with Negative Skin Tests

FINDING	NO. OF CASES	PER CENT
Family history of allergy	19	68
Past history of allergy	7	25
Blood eosinophilia	5	18 (average)
Positive ophthalmic tests	2	7
Positive nasal tests	4	14

blood eosinophilia comparable with similar findings in other types of human hypersensitiveness (Table 1). In the absence of positive skin tests, the results of the more delicate ophthalmic and nasal tests are recorded.

Contrary to what might be expected in this group, the incidence of positive ophthalmic tests was higher than that of nasal tests when performed with dry pollens. This close relation between the ocular mucosa and the shock organ merits further investigation.

Nineteen of these patients,—12 with asthma, 6 with hay fever and 1 with cough,—who were followed for a year or longer and who received the benefit of close supervision and treatment, were the subjects of the present report. There were 9 males and 10 females, with an average age of thirty-seven years. The average age at the onset of symptoms was thirty years, which is somewhat higher than the expected average in frank hay fever.

\*From the Allergy Clinic, Massachusetts General Hospital.  
 †Assistant in medicine, Massachusetts General Hospital, Chief of Allergy Clinic, Boston City Hospital.

In practically all cases, the symptoms extended over more than one pollen season: 9 patients complained of symptoms in spring, summer and fall; 6 in summer and fall; 3 in spring and summer; and 1 in spring and fall. This, again, is unlike the events in frank pollen disease, in which a single pollen sensitivity generally prevails. Evidently, aside from the fact that skin tests show these patients to be refractory, as a group they have other characteristics as well.

The management of these cases and the selection of pollens for treatment present a definite problem. In the absence of positive skin tests as a guide, one must draw chiefly on the history of the case and on experience with allergic patients whose skin tests are positive. On this basis, patients having symptoms during May and early June were considered sensitive to tree pollens, of which oak and birch are most important. Lesser offenders among the trees, such as elm, poplar, ash, hickory and others, were omitted from consideration because the periods of pollination are short, the dates overlapping in many cases, and because the amounts of pollen shed are comparatively small.

Patients suffering from early June to the middle of July were considered sensitive to grass pollens, and those having fall symptoms, from the middle of August to October, were designated as ragweed cases.

Other atmospheric offenders that prevail during the various pollen seasons and must be reckoned with are molds, particularly *Alternaria*, *Hormodendrum* and *Aspergillus*. Since the exact dates of their pollution in the air are not well defined, and in the absence of positive skin tests, their etiologic significance could not be determined.

Pollen dosage presents another problem for consideration. Most of these patients can tolerate large doses without any untoward reactions. Others, however, may have systemic reactions even from a small dose. Therefore, caution rather than experience is required in selecting the proper dose for the individual patient. Contrary to the procedure followed in frank pollen disease,—in which treatment is initiated with comparatively high dilutions and the doses are increased by 0.05 or 0.10 cc.,—in the nonreacting pollen group, the technic is somewhat different. The following is presented as a working basis, which, however, must be flexible in conformity with the individual needs of the patient:

Initial dose	0.1 cc. of a 1:500 dilution
Second dose	0.1 cc. of a 1:100 dilution
Third dose	0.1 cc. of a 1:30 dilution
Fourth dose	0.1 cc. of a 1:20 extract.

All further increases are made from the 1:20 extract until an arbitrary final dose of 1.0 cc. is reached.

Throughout the treatment, watch must be kept over possible systemic reactions; when these occur, the need of a more gradual increase in dosage and of a possible smaller final dose becomes apparent.

Since in the earlier cases a 1:10 pollen extract was used, for which the equally potent 1:20 extract was later substituted, all pollen doses were for convenience calculated on a 1:10 scale.

Table 2 is descriptive of the symptomatology, type of pollens, number of doses, the size of maximum dose and the results of therapy in each case.

TABLE 2. *Therapy and End Results in 19 Treated Patients.*

CASE No.	SYMPTOM	POLLENS	MAXIMUM DOSE (1:10) cc.	TOTAL No. OF DOSES	RESULTS
1	Asthma	Tree and grass	0.20	20	Good
2	Asthma	Tree and grass	0.75	21	Good
3	Cough	Grass and ragweed	0.65	22	Good
4	Asthma	Tree, grass and ragweed	0.40	24	Good
5	Hay fever	Tree, grass and ragweed	0.70	27	Good
6	Asthma	Tree, grass and ragweed	0.60	27	Good
7	Asthma	Grass and ragweed	0.85	29	Good
8	Asthma	Tree and ragweed	0.60	31	Good
		Averages	0.59	25	
9	Hay fever	Grass and ragweed	0.10	18	Fair
10	Hay fever	Grass and ragweed	0.50	20	Fair
11	Hay fever	Tree, grass and ragweed	0.70	27	Fair
12	Asthma	Tree, grass and ragweed	0.90	31	Fair
13	Hay fever	Tree, grass and ragweed	0.60	32	Fair
14	Asthma	Tree, grass and ragweed	0.45	35	Fair
15	Asthma	Tree, grass and ragweed	0.75	36	Fair
		Averages	0.57	28	
16	Asthma	Tree and grass	0.30	10	Poor
17	Hay fever	Tree, grass and ragweed	0.30	13	Poor
18	Asthma	Grass and ragweed	1.00	27	Poor
19	Asthma	Grass and ragweed	0.20	28	Poor
		Averages	0.45	20	

In addition, the average size and number of doses for patients with good, fair and poor results from treatment are included at the bottom of the respective columns. The estimation of end results in pollen therapy on the scale of good, fair or poor has been adopted because of its simplicity and fair amount of accuracy.

Table 2 shows further that patients with good and fair results received a higher average number of pollen doses and larger final doses than patients with poor results. This suggests a possible causal relation between the intensity of treatment and the end results. At the same time, patients who failed to obtain satisfactory results had a higher incidence of systemic reactions than those whose responses to therapy were more favorable (Table 3). These figures suggest that patients with poor results have a higher degree of "shock organ" sensitivity, and that with some modification in the

technic, improvement in this group may not be impossible.

Altogether, 15 of the 19 patients, or 79 per cent, were benefited by the treatment. These figures are impressive and emphasize the merits of

TABLE 3. *Results of Treatment in Relation to Systemic Reactions.*

RESULT OF TREATMENT	NO. OF CASES	SYSTEMIC REACTIONS	
		NO. OF CASES	PER CENT
Good .....	8	2	25
Fair .....	7	1	14
Poor .....	4	2	50

pollen therapy in patients whose skin tests are negative.

### DISCUSSION

The group as a whole is presented to illustrate a type of allergy that is masked by a lack of positive skin tests. However, the clinical characteristics of these patients—their symptomatology, their aptitude for allergy, their response to specific therapy and, finally, their tendency to systemic reactions from an overdose of pollen extract—leave no doubt that their etiologic group-*ing* is correct.

The important factor in this group is the seasonal incidence of the disease. The general tendency would be to place such patients among the undiagnosed or intrinsic cases whose symptoms are due to causes from within the body, but the proper appraisal of the disease opens an approach to specific therapy that promises some degree of success.

An example of such success is the patient in Case 2, whose seasonal asthma confined her to her bed each spring for a period of from six to eight weeks, but who has remained well with specific treatment; another example is the patient in Case 5, who was similarly affected each summer, but who has lost no time from work since treatment began. In Case 7, the patient collapsed and was in a state of unconsciousness in July, 1939, because of severe asthma, and was saved only through heroic treatment with adrenalin, an oxygen tent and so forth. In 1940, under pollen therapy, he had two mild attacks, which required no adrenalin. In these three cases, nasal and ocular tests to the offending pollens were negative.

The occurrence of clinical symptoms from the inhalation of small quantities of pollen in the air, in spite of negative ophthalmic or nasal tests, defies explanation.

Of particular interest is Case 3; for twenty years, the patient had had an intractable summer cough, lasting from the middle of June until the fall. Skin tests were negative, and ophthalmic tests doubtful. Treatment with extract of timothy and ragweed brought complete relief. In this case, cough was the presenting symptom, and pollens were the cause.

The occurrence of so many constitutional reactions (in 6 out of 19 patients) seems inexcusable, except that in the past, I have vainly attempted to treat similar patients with smaller doses. It was only in desperation that stronger doses were used, and only on the assumption that when skin tests are negative, the tolerance for pollen is high. In a measure, this is true, but it is also true that the shock organs, particularly the bronchi, have their own measure of tolerance, regardless of the response of the skin. The question then arises, What can be done to avoid such reactions? No definite answer can be suggested except the cautious increase of each successive pollen dose as treatment progresses. The local reactions to the injections in this group were few, often delayed in onset, and occurred only with doses close to 1.0 cc. of the extract. But even in these cases, the local reactions bore no relation to the systemic reactions, most of which occurred in the absence of local reactions.

Another point that merits discussion is the number of doses injected in each patient. Many of those in dilutions higher than 1:500 were undoubtedly superfluous. Yet, it is possible that the summation of the repeated injections ultimately bore results. Thus, in treating these patients, one may omit the lower dilutions, and safely start with a 1:500 extract. Beyond this, the advances must be cautious, and experience alone must be the guide in estimating further doses.

No explanation can be offered for the failures, particularly in those patients who experienced constitutional reactions. Evidently, the pollens used were specifically indicated, the dosage was carried to the point of tolerance and even higher, and yet the results were poor. The only consoling thought is that failures also occur in skin-sensitive patients, in spite of the most intensive treatment; however, in the skin-negative group the percentage of failures was higher.

In the final analysis, the mechanism of relief in pollen therapy is not clear, although the discovery of the blocking antibody in the serum of treated patients offers some ground for speculative thought.<sup>8</sup> Pollen therapy is justifiable chief-

ly on the basis of so many excellent clinical results. By the same token, it seems reasonable to treat the refractory group with pollen extracts if the history points to pollen disease. The broader application of these observations must find its way to the large number of patients with perennial allergy, who, in the absence of positive skin tests and lacking the seasonal element, present a difficult problem both in diagnosis and in treatment.

### SUMMARY AND CONCLUSIONS

Pollen disease in the absence of positive skin tests presents a definite problem in diagnosis and treatment.

A knowledge of the atmospheric flora in a given locality and of the dates of pollination makes a correct diagnosis possible.

Treatment given with corresponding pollen extracts offers relief in a high percentage of cases.

The technic of treatment is outlined, and the incidental systemic reactions are pointed out as possible complications.

Several characteristics of patients with negative skin tests are described, and emphasis is placed on the severity of their symptoms.

## NEW HAMPSHIRE MEDICAL SOCIETY

### PROCEEDINGS OF THE ONE HUNDRED AND FIFTIETH ANNIVERSARY

May 13 and 14, 1941

TUESDAY, MAY 13

THE scientific session of the New Hampshire Medical Society was opened at the Hotel Carpenter, Manchester, at two-thirty o'clock in the afternoon, with President Ezra A. Jones presiding.

Three papers dealing with fractures were presented, as follows: "Fractures of the Forearm and Humerus," Dr. Augustus Thorndike, Jr., Boston; and "Femoral Fractures," Dr. George W. Van Gorder, Boston; and "Fractures of the Foot and Ankle," Dr. Otto J. Hermann, Boston. This was concluded by a talk, "Glaucoma," by Dr. Paul A. Chandler, Boston.

WEDNESDAY, MAY 14

The morning session convened at eleven o'clock, with President Jones presiding.

The following remarks were made by the visiting delegates from other New England state medical societies:

DR. FRANK R. OBER, Boston: It is a pleasure to be here with you, and I bring the best wishes of the Massachusetts Medical Society to the New Hampshire Medical Society.

I am going to say only a word, which has to do with postgraduate teaching. A few years ago, the Massachusetts Medical Society established the New England Postgraduate Assembly, for the benefit of all doctors in New

England; your state, Maine, Vermont and Rhode Island voted to join the assembly, and last year Connecticut came in. Incidentally, Connecticut has conducted a clinical congress for a great many years—I think next year will be the sixteenth. I know of only one other state—Kansas—that has had meetings of this type for a longer period.

The program committee represents the hospitals and medical schools of Boston, the different states and the members of the assembly. The speakers are from outside Boston, and are chosen because they are outstanding in their fields of medicine.

The next meeting will be held on October 29 and 30. Last year, we had it in the middle of November, and it rained cats and dogs for the two days; the year before, it rained cats and dogs the first day. This year we hope for better weather.

We charge a fee that is supposed to cover the general expenses and those of getting the speakers; last year, however, we lost over \$600.

The meetings are held in Cambridge, at the Sanders Theatre, in Memorial Hall, Harvard University. We believe the assembly should be an entirely scientific affair; hence, there are no exhibits of any sort.

I hope that all of you will act as spark plugs in your district or county societies, and urge as many members to come to the next meeting in October as possible.

DR. WILLIAM T. ROWE, Rumford, Maine: The Maine Medical Association sends hearty greetings to the New Hampshire Medical Society at its one hundred and fiftieth annual meeting, and best wishes for a successful gathering.

You are, indeed, fortunate to be able to secure for your meetings some of the leaders of the medical world. Last year, as the Maine delegate, I had the pleasure of listening

to the president of the American Medical Association here in this auditorium, and today I hope to have the added pleasure of listening to the new president of the American Medical Association, Dr. Frank H. Lahey of Boston.

The annual session of the Maine Medical Association will be held at the Marshall House, York Harbor, on June 22, 23 and 24. On Sunday evening, we are planning to have a guest speaker who has recently returned from England. Monday and Tuesday mornings, the system of conferences will be continued. Monday and Tuesday afternoons, there will be guest speakers from outside Maine. Monday evening, there will be a reception in honor of the President of the Association and his wife, Dr. and Mrs. Thomas A. Foster.

The Maine Medical Association congratulates you on your long and honorable record. We invite you all to be with us at York Harbor at our annual meeting.

Dr. ARTHUR B. LANDRY, Hartford, Connecticut. I bring you greetings and best wishes from the Connecticut State Medical Society on this, your one hundred and fiftieth anniversary. You may celebrate your past rightfully because it has been a notable and a dramatic one, full of achievements.

I congratulate you, and all the more do I congratulate you because inherent in your past is the urge and vision that must regard this celebration as only a pause and a breathing spell, before you gain further momentum for the unfulfilled account that lies before you.

It is, alas, true that many celebrations of the past be come deadly, nursing complacency and anesthetizing fresh endeavor and conflict. Henry Ward Beecher tells the story of the dog that, in its puppyhood, chased a squirrel up a tree until he came to a hole in the tree, and that he spent the rest of his natural life barking up the hole of this tree. But that is not true of the members of this society, and certainly it is not true of the medical profession as a whole.

In these times there are many changes that demand intelligence and generous tolerance. Never was the opportunity so great for advance, service and achievement. If there ever was a time to follow St. Paul's challenge in our profession it is now, we should forget the things that are beyond and reach forward to those before us. So, let us press on toward the mark of our high calling.

We, of the State of Connecticut, will celebrate our one hundred and fiftieth anniversary next year, in Middle town, where the first meeting of the Connecticut State Medical Society was held. We invite you all to come and see us at that time, and we assure you of a very warm welcome.

Dr. ARTHUR H. RUGGLES, Providence, Rhode Island. To this most auspicious and historical occasion, I bring greetings and very best wishes from the Rhode Island Medical Society.

It is a great pleasure for one who originated in New Hampshire to return. I sometimes think that those of us who were careless enough to wander away live for the opportunity to get back here. I know that I always get a real thrill whenever I set foot in this state.

Dr. Frank H. Matthews, also a former resident of New Hampshire, and the other delegate from the Rhode Island Medical Society, is ill and could not come. He sends his official greetings to your society and to his many friends in New Hampshire.

I bring to all the members of your society an invitation to attend the summer meeting of the Rhode Island Medical Society, which is to be held at the Viking Hotel,

Newport, on May 28 and 29. Any of you who can come will have a cordial welcome.

I shall say one other thing. It seems to be that on this historic occasion for your society, we ought to emphasize one fact, and keep emphasizing it, namely, that there never has been a time in the history of the world when physicians need to stand together more firmly than at the present. We all realize some of the problems of social revolution through which we are going, and the world needs our clear thinking, our careful decisions and our united action that is why it seems to me most fortunate that in all our gatherings we can have representations from the various states, and that together we can listen to the papers and discussions, and that we can always hold curbstone consultations with each other, so that we may know the thoughts of the various groups and try, in our actions and as we face a troubled and important future, to have the medical profession stand together and think clearly.

Dr. LUCIUS C. KINGMAN, Providence, Rhode Island. When our society was founded, your society was just old enough to vote. When it was rumored around Rhode Island that you were to have your one hundred and fiftieth anniversary, there was a little lifting of eyebrows. Then, it was intimated that probably you had to gather in all the Indian medicine men in the community to get enough men to make a society. But, when it was pointed out that Rhode Island did not sign up with the Union until a year after New Hampshire did, they thought possibly there was something in it.

I have still another invitation to bring to you. Dr. Ruggles has already extended the invitation to you to attend our annual meeting at the end of this month at Newport, but I am going to invite you to come to our one hundred and fiftieth anniversary in 1962.

General Bowen then spoke as follows:

I should not wish to have this opportunity pass without appearing before the members of the medical profession in this state to express my appreciation of the wonderful contribution that the physicians have made to the success of the Selective Service System.

As you know, the United States Army is engaged in selecting men on a different basis than was ever done before. These men are not intended to go in for one year's service only, but they are intended to pass into the reserves and remain men who are capable of good field service for ten years. In other words, we are trying to pick men so well that they can remain in storage for that length of time, and that explains why there is so much insistence on the work of the medical profession. It is through the medical service that these men are passing to make this army that we are establishing the best anywhere. In doing that in New Hampshire, we have the services of about one hundred and eighty-five medical officers, all serving without compensation, either as examining physicians or additional examining physicians, members of the medical advisory boards or somewhere else in the service, from the top to the bottom, from the Board of Appeal right down the line.

The amount of work that has been done by these men has been tremendous. Since the registration last October, they have made about 3500 examinations, and these have been detailed examinations, in the course of which they have rejected approximately 45 per cent of the selectees.

That means a lot of work, and destruction, in many cases, of the doctor's regular practice. But, I want to say publicly to all who are here that I have never heard

one complaint from any physician; in fact, some of them have been so interested in this work that they have not even asked for assistance of any kind. In some cases, we have had practically to force a physician to take another man to help him.

In passing, I should also like to mention that we have now arrived at an answer to the great medical problem of the deferment of physicians, of interns and of medical students. This will not be done in a blanket way, but each case will be considered by its local board; and since we will probably know the requirements of the United States Army within the next few months, by next fall you may rest assured that the ranks of the medical profession will not be depleted, nor will the steady flow of young men into the profession, which you need so badly, be interrupted.

On behalf of the National Director, on behalf of His Excellency, the Governor of this state, on behalf of the staff guiding the work of the Selective Service System in this state, and on my own behalf, I thank you all very much. I thank the president of the Society for his continuous co operation with us in every possible way, and I thank the physicians for the wonderful help that they have given.

I know that we all see that at this time, as in the past, the physicians are ready to make their contributions, both now in preparing an army, and later on the field, if, unfortunately, this great country should be obliged to enter the war.

Captain Wheeler added the following:

General Bowen has asked me to read a few figures concerning the defects that were found, which might be of interest to the medical profession. The figures are correct up to about a month ago.

As General Bowen has said, approximately 45 per cent of those examined were found unqualified for general military service. Some of these were found qualified for limited service, and the others were disqualified.

Of those rejected, about 28 per cent were thrown out because of defective teeth alone. Furthermore, 41 per cent of those rejected had teeth sufficient to reject them, but had other causes, also. But, one might say that, without any other causes, nearly 70 per cent were rejected because of their teeth.

Nine per cent of those rejected were thrown out solely because of eye defects, and about 5 per cent for hernia. Twelve per cent of those rejected had muscular skeletal defects.

A number of men were rejected for so-called "mental causes"—mental deficiency, as well as the psychoses. Over 5 per cent were rejected solely for mental conditions; however, 9.3 per cent of those examined were mentally deficient or mentally defective in one way or another.

The morning session was concluded by an address by Dr. Frank H. Lahey, of Boston, the title being "The Management of Lesions of the Stomach, Duodenum and Jejunum."

The afternoon session convened at two o'clock, with Vice-President Charles H. Dolloff, presiding.

The Secretary, Dr. Carleton R. Metcalf, gave a résumé of the actions of the House of Delegates, and Dr. Deering G. Smith, delegate to the House of Delegates of the American Medical As-

sociation and chairman of the Committee on Medical Preparedness of the Society, repeated, in part, his report as given to the House of Delegates of the Society.

The report of the Trustees was then presented by Dr. Henry O. Smith.

##### BARTLETT FUND

Deposit: Portsmouth Savings Bank (\$352.11 of this is a permanent fund, the income to be "expended only for the benefit of medical science, as may be directed by vote of this society")	\$4,643 26
--	------------

##### PRAY FUND

Deposit: Strafford Savings Bank (\$1000 of this is a permanent fund, the income to be expended only for prize essays)	\$1,294 00
---	------------

##### BURNHAM FUND

Deposit: New Hampshire Savings Bank (\$1140 of this is a permanent fund, the income to be expended only for prize essays)	\$2,191.00
---	------------

##### BENEVOLENCE FUND

Deposit: New Hampshire Savings Bank (\$349.81 of this is accrued income available for the purposes of the fund)	\$4,224 50
---	------------

A prize of \$100 was awarded for a paper entitled "Scientific Medicine in General Practice" by "Edward L. Hale," pseudonym for Dr. Oliver S. Hayward, of New London, New Hampshire. It is expected that prizes will be offered in 1941-1942, and notice will be sent to the members of the Society in due time.

The accounts of the Treasurer of this Society have been examined and found correctly cast and properly vouched.

HENRY O. SMITH  
SAMUEL T. LADD  
FREDERIC P. LORD

Dr Stanley B Weld, of Hartford, Connecticut, then spoke concerning the National Physicians' Committee, and was followed by Dr Jones, who delivered the presidential address, entitled *Orthopedics in New Hampshire*. The scientific session was concluded by a talk, *'The Work of the Medical Examiner,'* by Dr William J Brickley of Boston.

The banquet was held at the Hotel Carpenter at six thirty o'clock, with Dr David W Parker, of Manchester, as toastmaster. Following the opening remarks of Dr. Parker, President Elect Charles H Dolloff, of Concord, and President Jones spoke briefly. Dr Harry H Amsden, of Concord, then gave an address, *"The Doctor of One Hundred and Fifty Years Ago"*. Dr Frederic P Lord of Hanover, spoke concerning the prominence of the Mussey family in the medical history of New Hampshire, and introduced William C Mussey, he then gave a short account of the equally prominent Smith family, and introduced Dr Henry O Smith, Dr Deering G Smith and Robert G Smith. Dr Henry O Smith, of Hudson, described the career of Dr Josiah Bartlett, the founder and first president of the Society, and introduced Mrs Levi S Bartlett and Mrs Lottie Goodrich the latter a direct descendant of the founder. Dr Marion Fairfield, of Nashua, then read the appreciation of Dr Bartlett pronounced by Dr Thomas W Luce, at the time of his retirement as president of the Society.

In passing out of the picture as the retiring president I want to use the time at my disposal in talking to you about the man who first held the office I am being relieved of today. It has long been the custom of most presidents of this society to refer to their predecessors in the office in some complimentary way. This seems to me a fitting thing to do because some very able men and, indeed, some very eminent men, have been presidents of this society. To my mind, however, no one in this long list of incumbents, covering the whole period of one hundred and thirty five years, has ever quite measured up to our first president, Josiah Bartlett.

His history is probably well known to most of you and its recapitulation at this time may seem trite. I have, however been led to select him as my theme tonight for two reasons. First, this happens to be the sesquicentennial of the Declaration of Independence, which he did so much to bring about, and next because I believe his story should be told here once in a decade or so by someone, lest we forget our great inheritance.

Josiah Bartlett, then, was born in Amesbury in 1729. At the age of sixteen, he went into the office of a relative, Dr Ordway, and began the study of medicine. This was some twenty years before our first medical school was established in Philadelphia, and physicians were made in those days just as carpenters and blacksmiths were made, by a five to seven years apprenticeship with a master.

Josiah had been well grounded in the three Rs and had a good elementary knowledge of Latin and

Greek, and he was a good student. He had the clinical advantages afforded by Dr Ordway's large practice and also the use of his very good library. He did a great deal of dissecting during the five years of his term with Dr Ordway, and he became a very proficient anatomist, also his notes on his study of plant life gave evidence of good knowledge in this field.

In 1750, when he was twenty-one years old, he settled in the town of Kingston and commenced a medical practice which he continued for forty five years. He was a close and careful observer and quite early in his medical career he discovered what he believed to be gross errors in the then accepted pathology and treatment of several diseases, and with a boldness which always followed his convictions, he inaugurated many medical reforms, some of which almost constitute marking stones of medical progress in New England. His crowning medical achievement from our view point, perhaps, was the founding of this society. He secured its charter, wrote its constitution and bylaws, and then, associating with himself eighteen other physicians of the state, all men of prominence in their profession, he formally organized this society on February 16, 1791. He was naturally made the first president, and was re-elected for four successive terms.

Quite early in life, he became interested in military affairs and gradually rose to be a colonel in the King's militia, and was at that time the highest ranking military officer in the state. His colonel's commission was recalled, and his house in Kingston was burned by a spy in 1774, because of his patriotic activities, but many of our New Hampshire soldiers who distinguished themselves under General Stark at Bunker Hill and Bennington, and at Burgoyne's surrender, and later under General Washington in the southern campaigns, received their military training from Colonel Bartlett.

While with Dr Ordway and during the early years of his professional life, he whiled away his spare time in reading law books. He somehow acquired a knowledge of the law, which, combined with his sound sense and judgment, was recognized in 1780 in his appointment as a justice in the Court of Common Pleas. In 1787, he was elevated to the Supreme Court of New Hampshire. When we recall the national reputations of some of the New Hampshire lawyers of his period, we have to believe that his standing as a justice must have been far from mediocre.

Josiah Bartlett frequently represented his town in the legislative assembly, and in 1775, he was elected to the Continental Congress. When the greatest state paper ever conceived by the mind of man came up for a vote of ratification, the roll was called by states—New Hampshire, the northernmost state, was called first and Georgia, the southernmost, last. Thus, Josiah Bartlett was the first member to vote yes for the Declaration of Independence, and after that document had been signed by the president of the Congress, John Hancock, the second to sign was Josiah Bartlett. This act has made him immortal, and yet it fell to his lot a few years later to render his country perhaps an even greater service. When the Constitution was submitted to the states, it encountered considerable opposition. It was necessary, if it survived, that nine states accept it. Eight had accepted it when our constitutional convention met in February, 1788, and as New Hampshire was the ninth state, the attention of the entire nation was directed to this assembly.

Josiah Bartlett, always a resourceful politician, was a member of that convention, and he ascertained quite early that the measure was bound to fail because so many of the delegates, particularly from the smaller towns, were under instruction to vote against it. He, therefore, secured an adjournment until the following June. He then began a very intensive personal campaign for the constitution and was rewarded, when the convention reconvened, by a 57 to 46 vote for its acceptance. So we may possibly owe to the energy and wisdom of Josiah Bartlett some of the greatly vaunted constitutional rights and privileges that we enjoy today.

New Hampshire was the first state to have a constitution of its own, and that constitution, under which we live and do business today, was very largely written by Josiah Bartlett. He was the first governor of the state under that constitution, and was re-elected for four successive terms. He was then elected a member of the United States Senate, but was unable to serve because of physical infirmities.

He brought up a family of twelve children. Three of his sons and seven of his grandsons became doctors of medicine.

All this I submit as a brief survey of some of the outstanding events in the career of a remarkable man.

Josiah Bartlett is described by his contemporaries as a tall man of fine figure, affable but dignified in his manner and very particular in his dress. He wore his auburn hair in a queue, a white stock at his throat, ruffles at his wrists, short clothes, silk hose, low shoes with silver buckles. One writer, the Rev. Dr. Rollins, describes his bearing as that of "an Athenian philosopher, fine and aesthetic, curiously mingled with Yankee shrewdness, cool and practical."

In Amesbury, the house in which he was born is owned and maintained by the Josiah Bartlett Chapter of the Daughters of the American Revolution. His bronze statue standing in the square was unveiled in 1888, and Whittier's poem, "The Signer," was written for the event. His picture hangs on the wall in our state house, and the town at the southern entrance to our beautiful Crawford Notch is named in his honor.

In the town of Kingston, on a slight elevation overlooking the village green, still stands the fine, old-fashioned house that he built and lived in, after his first house was burned in 1774. It has always been owned and occupied by his descendants. It is in a good

state of preservation and is literally filled with Josiah Bartlett's belongings. Its present mistress, Mrs. Levi S. Bartlett, is always glad to welcome anyone who may be interested and takes delight in showing the house and the doctor's things.

It seems to me that we, as members of this venerable society which he founded, as well as sons of the State and Nation which he helped to found, may well regard this fine old mansion as our particular shrine, to which we should feel in duty bound to make at least one pilgrimage, in humbleness of heart, and, as has been said by a former president, hope to gain from such an experience at least some degree of that rare devotion to our profession and to our country that characterized Josiah Bartlett.

Across the green from the house is the old tavern and in the rear of this is the village cemetery, in one corner of which a plain pile of cut granite marks the last resting place of the first president of this society. The inscription states that he died May 19, 1795, in the sixty-fifth year of his life.

And now, in closing, I want to read to you the last words of his message to this society as its retiring president. This was written and sent out from his sickroom in that old house in Kingston and was read at the annual meeting held in Concord in 1794. These words are, and perhaps were intended to be, as much a message for us of today, as they were for those members who listened to them as they were read, in this very place, one hundred and thirty-two years ago:

That the members of this Society may be useful to themselves and the public, and enjoy that exalted pleasure that arises from a consciousness that they have contributed to the health and happiness, not only of their patients, but, by communicating to others the knowledge and cure of disease, to the general happiness of the human race, is the ardent wish, Gentlemen, of your very humble servant, Josiah Bartlett.

Governor Robert O. Blood spoke concerning the increasing participation by the State in matters pertaining to medical care, and the program was concluded by Dr. Lahey, who recounted many of the current problems facing the medical profession in the United States.

## MEDICAL PROGRESS

### TREATMENT OF MENINGITIS<sup>6</sup>

MAXWELL FINLAND, M.D.,<sup>†</sup> AND JOHN H. DINGLE, M.D.<sup>‡</sup>

BOSTON

PRIOR to 1936, recoveries from acute bacterial meningitis due to organisms other than the meningococcus were quite rare, in spite of laborious and often heroic therapy of many sorts. The mortality in the meningococcal cases was likewise very high, in spite of the almost universal use of specific serums and other measures. The results reported<sup>1-3</sup> in several large series of cases are probably typical, although small groups of cases with more favorable results from various therapeutic procedures were occasionally reported.

Tripoli<sup>1</sup> summarized the results of different kinds of treatment at the Charity Hospital in New Orleans between 1925 and 1934. His series included 221 cases of meningococcal meningitis with a mortality of 65 per cent and 247 other cases of nontuberculous acute meningitis with only 3 recoveries. All the patients with meningococcal meningitis received antiserum intravenously and intramuscularly, but the lowest fatality rates (42 and 48 per cent) were obtained in those patients who received intraspinal and intracisternal injections in addition.

Lindsay, Rice and Selinger<sup>2</sup> reviewed 331 cases of meningitis treated at the Children's Hospital in Washington during the ten year period from 1924 to 1933. The mortality was 40 per cent in 58 cases of meningococcal infection, whereas only 3 patients recovered among 133 with other proved bacterial etiology after the tuberculous and the syphilitic cases were excluded.

Neal<sup>3</sup> summarized 3178 cases occurring in New York City during a twenty five year period prior to 1935. In this series, there were 829 cases due to bacterial agents other than the meningococcus or the tubercle bacillus, with only 24 recoveries. In an earlier paper, Neal and her associates<sup>4</sup> had reported 302 cases of meningococcal meningitis

for whose treatment they were responsible. These cases occurred during a five year period prior to 1931, and the mortality in this series was 18.3 per cent. Walsh,<sup>5</sup> however, estimated that the mortality from cerebrospinal fever in the United States from 1920 to 1936 averaged over 50 per cent.

As with most other serious acute bacterial infections, chemotherapy with the sulfonamide drugs has almost completely revolutionized the management and the prognosis in cases of acute purulent meningitis. The successes from chemotherapy alone have been so frequent and so striking by contrast with previous results that many of the specific therapeutic measures and other procedures formerly thought to be helpful and even essential are rapidly being discarded. In this report, we shall summarize the current opinions concerning the chemotherapy and specific serotherapy of acute meningitis due to some of the commoner bacterial agents, and shall consider the present status of some of the nonspecific therapeutic procedures previously employed. A more comprehensive review of the recent literature, particularly that dealing with meningococcal meningitis, has been prepared for publication elsewhere.<sup>6</sup> Keefer's<sup>7</sup> recent clinic also contains a summary of important features concerning the pathogenesis, diagnosis, prognosis and treatment of meningitis.

### GENERAL ASPECTS OF TREATMENT

#### *Meningococcal Meningitis*

Cerebrospinal fever has long been recognized as a "scourge of armies." This is due to the spectacular nature of the clinical manifestations and not to a high attack rate or to a high fatality rate. The disease usually strikes in an almost mysterious way, without warning, thus having a marked depressing effect on the morale of the military personnel.<sup>8</sup> During World War I, there were 5839 cases of meningococcal meningitis in the United States Army, with 2279 deaths.<sup>9</sup> The disease was also quite prevalent in this country during the late twenties, spreading from the West Coast through the Middle West, but tending to spare the cities of the Atlantic Seaboard.<sup>8</sup> In recent months, there have been a considerable number of

All articles in this series will be published in book form in the current volume of *Medical Progress*, Annals 1940 (Springfield, Ill.) no. 5. Charles C. Thomas Company 1941. \$4.00.

<sup>†</sup>From the Thorndike Memorial Laboratory, Second and Fourth Medical Services (Harvard) Boston City Hospital and the Department of Medicine and the Department of Bacteriology and Immunology, Harvard Medical School.

This study was aided in part by a grant from the William W. Willington Memorial Research Fund, Harvard Medical School.

<sup>‡</sup>Assistant professor of medicine, Harvard Medical School, chief, Fourth Medical Service (Harvard) and associate physician, Thorndike Memorial Laboratory, Boston City Hospital.

Instructor and Francis Weld Peabody Fellow in medicine and instructor in bacteriology, Harvard Medical School; assistant physician, Thorndike Memorial Laboratory, Boston City Hospital.

cases in Nova Scotia,<sup>10</sup> and in Great Britain some 12,500 cases were reported during 1940.<sup>11</sup> Further outbreaks are likely to occur in this country in the near future.

**Chemotherapy.** Soon after the recognition of the effectiveness of sulfanilamide against the hemolytic streptococcus, Buttle, Gray and Stephenson<sup>12</sup> reported that this drug was also effective against meningococcal infections in mice. Since that time, sulfanilamide and several of its derivatives have been used widely and effectively in the treatment of cerebrospinal fever in human beings. Reliable figures of case fatality rates with chemotherapy alone are difficult to obtain, however, for several reasons: there were wide variations in mortality rates, both with and without serum, before the introduction of chemotherapy; from many of the reports, it is not possible to determine the number of cases receiving any one kind of therapy, and many patients received more than one kind of treatment; some of the fatal cases have often been excluded for a variety of reasons; data concerning the factors that influence the outcome have not always been presented in adequate detail. Nevertheless, it is abundantly evident that chemotherapy alone is highly effective in curing this disease, even under the most unfavorable conditions.<sup>13, 14</sup>

From a tabulation of some of the recent reports, the mortalities in sulfonamide-treated cases of meningococcal meningitis, based on groups of from 200 to over 1000 cases, are estimated as follows: with sulfanilamide alone, 14 per cent; with sulfanilamide and antiserum, 25 per cent; with sulfapyridine alone, 8 per cent; and with sulfapyridine in addition to antiserum, 12 per cent. Only small numbers of cases treated with sulfathiazole have been reported to date,<sup>15-17</sup> but the results in these cases seem to compare favorably with those obtained with sulfapyridine. In view of the low concentrations of sulfathiazole that are obtained in the cerebrospinal fluid during treatment,<sup>18, 19</sup> it would seem either that this drug is highly effective in low concentrations or that the level of the drug in the cerebrospinal fluid is not by itself of particular consequence. At any rate, so far as meningococcal meningitis is concerned, the warnings against the use of sulfathiazole based on this factor do not now seem to be justified. Sulfadiazine has also proved to be as effective as any of the other drugs in the few cases in which it has been used.<sup>10</sup> Since, when properly used, sulfadiazine appears to be less toxic than the other accepted sulfonamides, it may prove to be the drug of choice in the treatment of meningococcal infections.

**Serotherapy.** The difficulties in evaluating the results of serotherapy alone in cerebrospinal fever have been pointed out in a previous progress report.<sup>20</sup> To determine with scientific precision whether, in actual practice, antiserum is of value as a supplement to sulfonamide therapy is almost impossible. This is obvious from a study of the data on which the mortality figures mentioned above are based, and also from a consideration of the difficulties involved in the use of serums. Combined therapy is usually reserved for the severest cases, or else antiserum is given as a supplement to the sulfonamides in individual cases only after it begins to appear that the sulfonamides alone have failed to effect the desired cure.

Banks<sup>21</sup> has been sufficiently impressed with the results that he has obtained with chemotherapy alone to take the view that serum therapy is now unnecessary even as an adjuvant to chemotherapy. Other results from Britain suggest, however, that the mortality under chemotherapy is still over 20 per cent.<sup>22, 23</sup> The accuracy of these figures is, of course, open to question. Experimentally, the combination of sulfonamide and antiserum is more effective in curing meningococcal infections in animals than either agent alone.<sup>24</sup> Until more convincing data become available, therefore, it seems appropriate to reserve the immediate use of antiserum as a supplement to chemotherapy for the very severe or the apparently fulminating cases. It is particularly recommended for patients in coma in whom bacteremia is suspected. In other cases, antiserum need be employed only when there is no definite objective evidence of marked improvement after twenty-four to forty-eight hours of adequate chemotherapy. In any event, the serum used should contain antibodies specific for the infecting strain, and should be given intravenously in large doses with the usual precautions. Intrathecal administration should probably be avoided, at least until one is convinced that the disease is not being controlled adequately with drugs and intravenous antiserum.

The relative merits of antitoxin and antibacterial serum are still undecided. Hoyne<sup>25, 26</sup> advocates the use of antitoxin, although experimentally it appears to show no properties other than those due to the antibacterial immune bodies that it contains.<sup>27-29</sup>

Certain details concerning therapeutic procedures and diagnostic methods will be considered later.

### *Streptococcal Meningitis*

The mortality in cases of streptococcal meningitis has been reduced from over 95 per cent to less than 35 per cent by the use of sulfonamide

drugs<sup>30-33</sup> Sulfanilamide was the first drug to be used in this disease and, since it has proved highly effective, is still preferred by most physicians. Sulfapyridine is probably more effective, and successes with it have been reported. The use of other sulfonamides has not been reported in sufficient numbers of cases to warrant any opinions. Sulfathiazole should probably not be used because it is less effective against the streptococcus, in addition to the fact that high levels of this drug are difficult to maintain even in the blood. Sulfadiazine has proved to be highly effective in some other streptococcal infections<sup>34</sup> and will probably become the drug of choice, but data concerning its use in meningitis are not yet available.

Recoveries under sulfonamide therapy have been reported not only in meningitis caused by beta-hemolytic streptococci, but also in cases due to *Streptococcus viridans*<sup>35-37</sup> and even in isolated cases due to anaerobic streptococci.<sup>38</sup>

Antistreptococcus serums are probably of little or no value. Scarlet-fever antitoxins or convalescent serums, however, have been employed in some cases of postscarlatinal or other streptococcal meningitides. Apparently beneficial results have been reported from their use either alone or as a supplement to chemotherapy.<sup>39-40</sup> They are probably best reserved for patients with severe toxemia, especially when a rash is present.

### *Pneumococcal Meningitis*

There can be little doubt that almost all the numerous cases of recovery from pneumococcal meningitis that have appeared in the literature during the past four years are attributable directly to the use of sulfonamide drugs, since only isolated patients were previously known to survive this disease. Several authors,<sup>41-46</sup> in reviewing the recent literature, have estimated the mortality in sulfonamide treated cases to be about 35 per cent. This seems to us to be a deceptively low figure, since the great majority of failures remain unreported. Our recent experience suggests that the gross mortality in unselected cases receiving sulfonamide therapy, with or without other measures, is more nearly 80 per cent. Recoveries, however, have been reported in very severe and bacteremic cases,<sup>47</sup> in infants,<sup>48-50</sup> and even when the disease is complicated by cavernous sinus thrombosis.<sup>51</sup>

Specific antipneumococcus serums, alone or supplemented by various forms of drainage, may have been responsible for some recoveries prior to the introduction of sulfonamide therapy.<sup>42-52-54</sup> In experimental Type 1 pneumococcus meningitis in

rats, a greater percentage of recoveries may be obtained from the combination of specific antiserum and sulfanilamide than from either agent used separately.<sup>55</sup> This is difficult to demonstrate in human cases, although many of the recent reports of recoveries suggest that antiserum may have played a significant role when used to supplement chemotherapy.<sup>42-45-48-50-59</sup> The antiserums were given intravenously in all cases, but intrathecal injections, with or without complement, were used in some.

Sulfanilamide, which is known to have only relatively slight bacteriostatic action against the pneumococcus, has apparently been solely responsible for a number of the reported recoveries.<sup>46, 60</sup> It is our belief that in such cases the immunologic conditions were favorable, or that the organisms were highly susceptible or that both these factors were operative. Finland and his co-workers,<sup>53</sup> just before the introduction of sulfapyridine, reviewed the immunologic aspects of pneumococcal meningitis and outlined a therapeutic regime based on what was then known of the action of sulfanilamide and on the supposed mechanism of recovery in sulfanilamide treated cases. This regime included intensive treatment with sulfanilamide supplemented by intravenous antiserum and the intrathecal injection of antibodies and complement. It was realized that the administration of antibody probably was not essential in all cases and that, in practice, the intrathecal treatments would be necessary only in selected cases. It was to be expected, of course, that the introduction of more powerful antipneumococcus sulfonamides would reduce the necessity for serum therapy in many cases. Indeed, recent experience has indicated that a high percentage of recoveries may be expected from chemotherapy alone if intensive treatment with such drugs is undertaken from the beginning. Thus, the intravenous use of sodium sulfapyridine to initiate treatment and to maintain high blood concentrations during the first one or two days of therapy was probably responsible for the large proportion of recoveries in some of the recent reports.<sup>47, 61</sup>

Data on the uses of sulfathiazole and sulfadiazine in pneumococcal meningitis are scant, and judgment concerning the value of these drugs must therefore be reserved. Sulfadiazine seems to be advantageous, since it is effective in other pneumococcal infections and higher levels can be maintained with relatively fewer toxic effects when it is properly used.

Ross<sup>62</sup> reported a case of pneumococcal meningitis in which "drug resistance" was apparently acquired in the course of two or three days

of treatment with sulfapyridine. This occurrence is probably quite rare. Schmidt and Sesler<sup>63</sup> have recently shown that pneumococci that have become resistant to sulfapyridine are just as susceptible to hydroxyethylapocupreine as the parent strains. Since it has been shown that pneumococci which have become resistant to one effective sulfonamide are equally resistant to others,<sup>64, 65</sup> it may be necessary to resort to hydroxyethylapocupreine in cases in which sulfonamide fastness can be proved.

### *Influenza-Bacillus Meningitis*

The gross mortality in untreated cases of this disease is over 90 per cent, and the most vital single prognostic factor is the age of the patient. Almost all infants less than two years of age succumb.<sup>66</sup> Of the six known types of *Haemophilus influenzae*, Type B produces the great majority of the meningeal infections in infants and children. Most of those in older patients are probably due to other types or to the rough strains normally found in the respiratory tract. It seems likely that many of the spontaneous recoveries and the recent successes with chemotherapy alone occurred in patients infected with these rough or respiratory strains. There is, of course, no relation between influenza-bacillus meningitis and epidemic influenza, the latter now being known to be due to a specific virus.

Although there are a number of reports of recoveries from sulfonamide drugs alone, most of these occurred in the older age groups. The sum total of the results, although encouraging, is not very striking.<sup>56</sup> Many observers failed to obtain any favorable results with the use of drugs only, and that has been our experience. Final judgment on the effectiveness of sulfonamides alone, however, awaits more extensive data.

During the past few years, specific antiserum prepared in horses has been used intravenously and intrathecally, both with and without complement, in the treatment of meningitis due to the Type B influenza bacillus. Although the gross mortality may have been reduced to about 80 per cent,<sup>67</sup> the results in general have been far from satisfactory. More recently, however, rabbit antiserum specific for Type B has been used with encouraging results.<sup>68, 69</sup> Most of the patients treated with rabbit antiserum received chemotherapy in addition, and the role of each of these agents is thus difficult to evaluate. Davies<sup>69</sup> has treated a few patients with rabbit antiserum alone, and his results seem to indicate that this single agent may be as effective as the combined therapy.

The treatment recently outlined by Alexander<sup>56</sup> is as follows: sulfanilamide should be administered

immediately; fluids should be forced for three hours; and the equivalent of 25 mg. of antibody nitrogen intrathecally and 50 to 75 mg. of antibody nitrogen in a slow intravenous drip diluted in physiologic saline, Ringer's or sulfanilamide solution, should be given. The object is to neutralize all the free antigen and to establish and maintain an excess of antibody in the blood and cerebrospinal fluid. Such an excess is present when the serum gives rise to capsular swelling with the homologous organisms, or when the skin reaction to the specific polysaccharide is positive.<sup>70</sup> It is not certain whether the intrathecal treatment is essential. Information concerning the relative merits of the various sulfonamides is also lacking.

### *Staphylococcal and Other Bacterial Meningitides*

Recoveries from staphylococcal meningitis have been reported from the use of sulfanilamide,<sup>71, 72</sup> but successes have been more frequent with the use of sulfathiazole.<sup>73-77</sup> There have been 2 recoveries with sulfathiazole treatment at the Boston City Hospital. Sulfadiazine may also be useful in this condition, since it is highly effective against the staphylococcus.<sup>34</sup> Lyons<sup>78</sup> reported 2 cases of bacteremic cavernous-sinus thrombophlebitis treated successfully with a combination of sulfathiazole and heparin. One of these patients had clinical signs of meningitis that were confirmed by lumbar puncture.

Isolated cases of meningitis due to a large variety of other bacteria have been treated successfully with various sulfonamide drugs. These have included, among others, infections with colon bacilli,<sup>79</sup> Salmonella organisms,<sup>80</sup> Friedländer's bacillus,<sup>81</sup> gonococcus<sup>82</sup> and *Micrococcus tetragenus*.<sup>83-85</sup> Various sulfonamides have been used in these cases, either singly or in succession.

### DIAGNOSIS

The final etiologic diagnosis in any case of meningitis must be made on the basis of isolation or immunologic identification of the organism. The recent use of certain laboratory technics, mentioned below, permits an immediate final diagnosis in some cases. With the pneumococcus, for example, final diagnosis of both the organism and its type may be made merely from a stained smear and from capsular swelling with rabbit typing serum.

Clinical differentiation of the various etiologic types of meningitis is usually not possible. Certain general statements, however, may be made. During an epidemic of cerebrospinal fever, if evidences of purulent meningitis are present, the most probable etiologic agent is the meningococ-

cus, and the patient should be so treated, even though organisms are not found. Meningitis associated with otitis or mastoiditis is most probably due either to the pneumococcus or to the streptococcus. When an upper respiratory infection precedes meningeal involvement, the likeliest organisms are the pneumococcus, the streptococcus and, in children, the influenza bacillus. If furuncles are present on the face or elsewhere, staphylococcal infection is probable. It should be remembered that in infants and young children the influenza bacillus is being recognized as one of the most frequent causes of meningitis.

Although primary meningitis is usually due to a single organism, mixed infections may occur. These may be either simultaneous or consecutive infections. Such mixed infections are rare and, when they occur, usually follow primary infections outside the central nervous system.

The etiologic diagnosis is made in the usual way by cultures of the cerebrospinal fluid, the blood and pus from focal infections. Several recent techniques have facilitated an early diagnosis. The capsular swelling reaction may be carried out directly on the spinal fluid, on its sediment or on the initial culture after the morphology and staining characteristics have been determined by the methylene blue and Gram's stains. This method is of particular value with the pneumococcus, influenza bacillus<sup>50</sup> and Type 1 meningococcus.<sup>57</sup> The technique is similar in all respects to that employed in typing pneumococci in sputum. The precipitin test, employing specific antiserum and the clear supernatant spinal fluid, may be of value. This procedure may be used not only for etiologic identification of the causative organism, but also for typing the pneumococcus and the influenza bacillus. The test has also been employed in meningococcal infections, but in these direct typing may be complicated by the presence of the group-specific C substance.<sup>58</sup> In some patients, the infecting organism may be obtained from cultures of the nasopharynx early in the disease. The meningococcus is almost always found there in cases of cerebrospinal fever.<sup>59</sup> Mueller and Hinton<sup>60</sup> have recently described a simplified medium for the cultivation of the meningococcus. This medium has proved satisfactory for the primary isolation of gonococci and meningococci.<sup>10</sup> The growth of meningococci is facilitated by increased tension of carbon dioxide, which may be accomplished simply by the use of a candle jar.<sup>91</sup>

#### FOCAL INFECTIONS

The elimination of focal infections is of the utmost importance because of the tendency of men-

ingeal infections to become refractory to therapy if such foci are not removed. If the focus is apparent and if the local reaction is sufficiently advanced, immediate operation should be carried out for the relief of pressure and evacuation of pus. Often, however, it is difficult to localize the focus. In a recent article, Keefer<sup>7</sup> has indicated a number of signs that aid in the differential diagnosis. In general, chemotherapy should be instituted for twelve to twenty-four hours before operative procedures are undertaken, and should be continued for several days thereafter. The extent of the operation should be sufficient to eliminate nonvital tissue, particularly necrotic bone. Cultures should be made from all purulent foci at the time of operation.

#### LUMBAR PUNCTURE

The present tendency among some clinicians who are treating patients with meningitis is to avoid doing lumbar punctures, even to the extent of eliminating the procedure completely. This is an extreme view that is probably not justified. First of all, an initial lumbar puncture is necessary to establish the diagnosis of meningitis and to determine the etiologic agent. This is still extremely valuable to ensure the choice of the most effective drug and of the specific serum. With the usual precautions, the procedure does not jeopardize life or interfere with the subsequent recovery of the patient. In a recent review, Pray<sup>62</sup> found that lumbar puncture is not a significant factor in inducing meningitis, even in bacteremic patients. His data suggest that there may be a greater risk to the patient through failure to recognize the presence of meningitis if this procedure is not carried out. The first spinal fluid should be collected aseptically in separate tubes for culture and for chemical determinations. Estimation of the glucose content is the most valuable of the chemical determinations, since a low level is consistently found in bacterial infections. Total and differential cell counts should also be carried out, since they are of aid in distinguishing bacterial infections from those due to other agents. Thus, in tuberculosis, syphilis and the virus diseases (lymphocytic choriomeningitis, equine encephalomyelitis, St. Louis encephalitis and so forth), mononuclear cells predominate. In the course of differential counts, typical organisms are sometimes recognized in torula infections.

Lumbar puncture should be repeated for specific indications: for relief of the signs and symptoms of increased cranial pressure; to determine the progress of the case; to establish cure; for the diagnosis of relapse or recurrence; and for intra-

thecal therapy with antiserum when other methods of therapy fail.

### CHOICE OF SULFONAMIDE DRUGS

It should be clear from what has already been said that all patients with acute bacterial meningitis should receive sulfonamide therapy, but no hard and fast rule can be set down regarding the choice of drugs or the indications for specific serums and for other measures. The number of adequately studied cases is too small to warrant definite opinions. This is particularly true of the use of sulfadiazine in all kinds of meningitis and of all the drugs in infections due to influenza bacillus and the less common organisms. With these reservations, the following is our own tentative order of preference of sulfonamide drugs for various kinds of acute bacterial meningitis:

CAUSATIVE ORGANISMS	ORDER OF CHOICE			
	SULFADIAZINE	SULFATHIAZOLE	SULFAPYRIDINE	SULFANILAMIDE
Meningococcus	1	3	2	4
Streptococcus	1	4	2	3
Pneumococcus	1	3	2	4
Influenza bacillus	?	?	?	?
Staphylococcus	1	2	3	4
Gram-negative bacilli	1	2	3	4
Other pyogenic organisms	1	2	3	4

### INDICATIONS FOR THE USE OF SPECIFIC ANTISERUMS

Regarding the use of specific antisera as a supplement to chemotherapy, there is considerable disagreement among competent authorities. In our opinion, much depends on the particular conditions presented in each case. The following factors must be considered: the availability of potent specific antiserum against the infecting strain; the severity of the disease—severe cases may proceed so rapidly to a fatal outcome that one cannot afford to temporize, and it is probably better to be wasteful of serum than to regret having missed the opportunity to use it; the response of the patient to adequate doses of sulfonamides; when foci of infection prevent an adequate response to drugs, specific serums are useful, not in preference to removal of these foci but as an additional measure.

With these factors in mind, we now believe that the following recommendations are justifiable. Antimeningococcus serums should be given to patients with Type 1 infections as soon as the etiologic diagnosis is made only when the disease appears to be severe or fulminating. In other cases, such serums may be used if the infection fails to respond to adequate chemotherapy within twenty-four to forty-eight hours. A favorable response is indicated by the disappearance of fever, the failure to recover organisms from the cerebrospinal fluid and the return of the level of

sugar in the cerebrospinal fluid to normal. In meningitis due to pneumococci of known types, homologous specific rabbit antisera should be used under the same conditions. All patients with Type B influenza bacillus meningitis should receive specific rabbit antiserum as soon as the organism is identified. Scarlet-fever antitoxins or convalescent serums may be used in severe and toxic streptococcal meningitis, particularly if it is associated with a rash or if it occurs in the course of scarlet fever or as a complication of that disease.

### DOSAGE AND ROUTE OF ADMINISTRATION OF DRUGS AND ANTISERUMS

The recent trend in the dosage of sulfonamide drugs is to give large amounts during the early stage of treatment, to try to maintain as high a level as is consistent with safety and comfort until the infection is well under control, to give fairly large amounts of fluids (3000 to 4000 cc. a day) and to continue drug treatment in the same or in slightly reduced doses for fairly long periods, to ensure against relapses.

The intravenous use of 0.8 per cent sulfanilamide in physiologic saline solution or of a 5 per cent solution of the sodium salts of the other common sulfonamides in distilled water is usually recommended. It is used for the initial dose and for the first twenty-four to forty-eight hours of treatment in all patients and also later in those who vomit excessively or fail to maintain adequate blood levels. We have preferred to use the sodium salts of the sulfanilamide derivatives dissolved in physiologic saline solution—1 to 2 per cent for intravenous use (larger concentrations precipitate out at room temperature) and 0.5 to 0.7 per cent for subcutaneous injections. The latter route is preferred for all but the initial injection when parenteral therapy is desired, and, in our experience, this produces no local reactions. The daily dosage is 6 to 9 gm., depending on the weight, for each of the drugs. This total amount is given as the initial intravenous injection, and a similar amount is given daily in three equal portions at eight-hour intervals for sulfanilamide, sulfapyridine and sulfathiazole, and in two equal parts every twelve hours when sulfadiazine is used. Oral administration is used as soon as the condition of the patient permits, and the daily dose is then given in six equal parts at four-hour intervals. Treatment is usually continued after complete clinical and bacteriologic evidence of recovery for two to five days in meningococcal infections, for ten to fourteen days in pneumococcal and streptococcal cases, and for two to three weeks in all other cases.

Intrathecal injections of sulfanilamide or of sodium sulfapyridine are still recommended by some authorities, but most of them caution against the use of sulfonamides by this route. There is some evidence from the recent results in sulfithiazole-treated cases to suggest that the concentration of drug in the spinal fluid may not be of significance per se, although this point is not yet proved.

When specific serums are used, they should be given intravenously (or intramuscularly, if necessary). The amount should be such as to establish and maintain an excess of antibody in the circulating blood. This may be demonstrated in infections due to pneumococci and influenza bacilli by capsular swelling of the patient's organism in his serum or by the immediate positive skin test with the homologous type specific polysaccharide.<sup>70</sup>

Intrathecal injections of serum are probably not necessary in most cases, and some experienced physicians now advise against their use under any circumstances. We believe that the intrathecal use of antiserum should be reserved for patients who fail to respond favorably to adequate chemotherapy and intravenous serotherapy, thirty-six to forty-eight hours being allowed to elapse after adequate intravenous therapy. The advisability of the additional use of complement (fresh human serum) with intrathecal antiserum seems to be very debatable at present. In pneumococcal meningitis in adults, both antibody and complement may be given intrathecally in the least irritating form by using fresh serum obtained from the patient after a sufficient excess of antibody has been established by intravenous therapy.<sup>71</sup>

### COMPLICATIONS

Complications of meningitis have been remarkably rare in patients who have recovered following sulfonamide therapy. Deafness is still the most frequent complication in the cases of cerebrospinal fever and has also been observed in patients recovering from pneumococcal meningitis. Hydrocephalus is also seen in infants recovering from all kinds of meningitis. Relapses are not infrequent. The diagnosis and treatment of the relapse are essentially the same as those of the original infection.

### PROPHYLAXIS

For the prevention of epidemics of cerebrospinal fever in military forces, Mink<sup>93</sup> and Zinsser<sup>94</sup> have proposed gradual mobilization and "hardening" of new recruits. Lybourn<sup>95, 96</sup> advocates the search for and isolation of chronic meningococcal

carriers. Treatment of carriers with antiseptic sprays<sup>90, 97</sup> has been attempted, but the results are not conclusive. Sulfonamide drugs have been tried recently with some encouraging results<sup>98, 99</sup> Penicillin as a snuff<sup>100</sup> and tyrothricin as a spray<sup>101</sup> are now receiving a trial for the eradication of carriers.

The prevention of pneumococcal and streptococcal meningitis depends on the care of foci of infection and of injuries in and about the head. The use of sulfonamide drugs is recommended in the treatment of otitis and mastoiditis and also during and after all operations in which the cranial cavity is or may be entered.

CASE RECORDS OF THE  
MASSACHUSETTS GENERAL HOSPITALANTE-MORTEM AND POST-MORTEM RECORDS AS USED  
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., Editor

## CASE 27471

## PRESENTATION OF CASE

A thirty-year-old man was admitted because of increasing difficulty in breathing.

The patient had been well until a month before entry, when there was sudden onset of cough, productive of purulent sputum. Nine days later, night sweats and chills appeared. When admitted to a sanatorium three days later, the patient was acutely ill and dyspneic, with rapid pulse and high fever. There was dullness throughout both lung fields, with a few medium rales in the left. On the fifteenth day of the illness, the blood showed a red-cell count of 4,950,000 with 85 per cent hemoglobin, and a white-cell count of 4400 with 79 per cent polymorphonuclears, 9 per cent lymphocytes, 11 per cent monocytes and 1 per cent basophils. A week later the white-cell count was 4500, and three days after that it rose to 6400 with 91 per cent polymorphonuclears. The sedimentation rate was 8 mm. The tuberculin test was negative up to 1 mg. The urine was essentially normal. Culture of the sputum showed mixed organisms, with staphylococci predominating; on another examination, a pure growth of hemolytic staphylococcus was isolated. Tubercle bacilli could not be found by concentration tests. Agglutination tests for typhoid and paratyphoid fevers, undulant fever and tularemia were negative. A course of sulfathiazole was given from the twentieth to the twenty-seventh day of the illness, and a blood level of 4 mg. per 100 cc. was attained. The drug was discontinued because of the appearance of a rash, and because of the absence of benefit. The patient continued acutely ill and febrile. His pulse ranged from 120 to 138, with respirations from 46 to 48. There was increasing cyanosis and dyspnea.

The past and family histories were not of significance.

On admission, the patient appeared thin and wasted. The skin and mucous membranes were quite cyanotic. The lips were covered with sordes, and the nostrils bore crusted hemorrhagic lesions. The trachea and heart were displaced to the left. Loud wet rales were heard over each upper-lung

field, with loud tubular breath sounds, and resonance was preserved in these areas. There were small moist rales in the lower two thirds of the right chest, with absence of breath sounds and with percussion dullness. A pleural friction rub was heard at the left base. The heart sounds were obscured by the lung noises. The abdomen was slightly tympanitic. Rectal examination was negative. There was well-defined pitting edema of both legs. The calves were soft, cool and free from tenderness.

The temperature was 102°F., the pulse 138, and the respirations 50. The blood pressure was 120 systolic, 75 diastolic.

Examination of the blood showed a white-cell count of 15,000 with 80 per cent polymorphonuclears. The red-cell count was essentially as noted in the other hospital. The nonprotein nitrogen of the blood was 23 mg. and the total protein 4.5 mg. per 100 cc.; the chlorides were 88 milliequiv. per liter. The van den Bergh reaction was 2.4 mg. per 100 cc., biphasic. The urine showed + tests for albumin, diacetic acid and bile. The sediment contained occasional white cells. The sputum grew *Staphylococcus aureus*.

A roentgenogram of the chest showed a large amount of fluid in the right pleural cavity, obscuring the right diaphragm and costophrenic angle, and extending upward in the axillary line as far as the apex. Dense consolidation radiated from the hilus on each side. The left pleural cavity seemed free of fluid. There was no evidence of cavitation.

A right thoracentesis yielded 1320 cc. of thin, free-flowing, yellow, slightly turbid fluid from which *Staph. aureus* was grown. The patient's respirations at once became less labored, and his color improved, changing from blue to pink. He was given oxygen, however, and started on sulfadiazine. Several hours later, he became irrational, and required restraint. The next day, trocar thoracotomy was performed, with drainage of about 600 cc. of fluid in twenty-four hours. The patient seemed improved. A blood transfusion was given and was repeated on the fourth hospital day. At this time, there was much emphysema of the subcutaneous tissues about the trocar wound. The edema of the legs extended as high as the sacrum. The urinary output for the day was only 330 cc., with a specific gravity of 1.032 and with a ++ test for albumin. It was thought that the concentration was related to the therapy, since a sulfadiazine blood level of 10.8 mg. per 100 cc. had been attained. At this time, a roentgenogram of the chest showed numerous hazy areas of in-

creased density in the portion of the right lung that had previously been obscured by fluid.

On the sixth hospital day, a firm, slightly tender mass was palpated in the splenic area, extending two to three fingerbreadths below the costal margin, and descending with respiration. Two days later, this mass reached four fingerbreadths below the costal margin. The liver edge was not palpable. Repeated transfusions were given. The patient remained comfortable as long as he was kept in an oxygen tent. On the eighth hospital day, the temperature began to spike from 99 to 104°F. Late on the tenth day, he again became increasingly dyspneic and cyanotic. The respirations fluctuated from 50 to 60, and the pulse from 150 to 160. There was an increase in moist rales throughout both lung fields, without extension of the mediastinal shift. Tourniquets to the extremities gave no apparent relief. The patient became irrational and unmanageable. On the twelfth and last hospital day, he was quite unresponsive. After an apparent brief convulsion, he was found to have a stiff neck. The head was fixed toward the left. There was cogwheel rigidity of muscles. The eyes were held open, and the pupils were unequal, reacting sluggishly. The fundi were normal. A lumbar puncture gave clear fluid, under an initial pressure of 100 mm. of water. The fluid contained 2 or 3 lymphocytes per cubic millimeter. In the last hours, the right pupil dilated and became fixed. There were choreiform movements of the arms and legs. Respirations gradually ceased.

#### DIFFERENTIAL DIAGNOSIS

DR. WILLIAM B. BREED: I should like, first of all, to simplify this story and follow it through more or less as a straightforward acute upper respiratory infection, with purulent staphylococcal bronchopulmonary infection; and I think we can do that, particularly if we take at face value the sudden onset of disease one month prior to entry.

Apparently, the patient had an acute upper respiratory infection, with sudden onset, which progressed; he probably developed a bronchial fistula, with empyema due to *Staphylococcus aureus*. Because of this illness, he did develop some avitaminosis. The serum protein was low, perhaps because of a nutritional factor.

Certain things about this story, if one reads it over a number of times, need explaining. The first is the leukopenia found in another hospital; another is the x-ray picture, which I am not clear about and which I want cleared up. Still another is the appearance of a mass under the left costal margin in the region of the spleen, which I think

we must accept as an enlarged spleen. Moreover, involvement of the central nervous system cannot be explained on the basis of acute fulminating bronchopulmonary infection alone. Before coming here, I asked one of our hematologists if, from the record, he could say that this leukopenia, which is reported with 11 per cent monocytes and a high polymorphonuclear count, indicated some underlying blood dyscrasia, such as lymphoma or aleukemic leukemia. He replied that it could represent such a condition, but that no such diagnosis could be made from the blood report alone. I agreed with that. However, I do think that we must consider the initial leukopenia with a monocytic increase as possibly being important in the fundamental diagnosis.

Now I should like to get more information on the x-ray findings.

DR. AUBREY O. HAMPTON: I am afraid I am not going to give you as much information as you would like. Almost any radiologist who saw these films would first think of pulmonary edema, because any type of pneumonia that would advance to that degree is seen only post mortem. I do not believe that a patient with pneumonia, other than tuberculous pneumonia, of that extent could still be alive, particularly for so many days.

DR. DONALD S. KING: The films taken in the sanatorium two weeks previously looked like that.

DR. BREED: Did you see them?

DR. KING: Yes.

DR. HAMPTON: I cannot be sure that there are abscesses in the lungs. Pulmonary edema, I think, should be ruled out because it did not change enough in the whole period of ten days. The most definite change occurred when they drained the fluid in the pleural cavity.

DR. BREED: Do you think that the patient had pleural sepsis with bronchial fistula?

DR. HAMPTON: The pleural fluid was not true pus, was it?

DR. CHAMP LYONS: It was a thin fluid, which on culture gave a heavy growth of *Staph. aureus*.

DR. HAMPTON: I should not expect it to have been real pus, because when it was drained the lung promptly expanded.

DR. BREED: And there was no bronchial fistula?

DR. HAMPTON: I do not believe so. I do not see any enlarged lymph nodes. In one of the films, there is a gas bubble, probably very high in the splenic flexure. I doubt very much if the spleen was enlarged. I think one would have to call this chronic bilateral pneumonia, with fluid in the right pleural space.

DR. BREED: There are no multiple abscesses?

DR. HAMPTON: I cannot be sure. These small areas of diminished density are not clear enough for me to make a diagnosis. There is overlying air in the pleural cavity—it might be interspersed between adhesions or fibrin.

DR. BREED: It is very difficult to believe this man was entirely well a month before entry into the hospital.

DR. BREED: What was his occupation?

DR. TRACY B. MALLORY: He was a tube annealer.

DR. BREED: That does not help. I suppose a tube annealer is not a candidate for pneumoconiosis.

DR. HAMPTON: The diagnosis would have to be acute silicosis if the lesion were due to dust.

DR. BREED: I think it is obvious that this man was not completely in good health one month previous to entry, when he had a sudden onset of cough followed by nine days of sweats and chills; and I am therefore prepared to make a few conclusions about the underlying lesions. I can assure you, however, that it will be mostly guesswork because there is no accurate laboratory evidence.

DR. HAMPTON: I now have the film taken in the sanatorium a month before the one I previously demonstrated. The patient obviously had considerable pulmonary disease at that time. It started out as small and large rounded areas of density. There were some small miliary lesions.

DR. BREED: Could they be multiple staphylococcal abscesses?

DR. HAMPTON: I do not believe so.

DR. BREED: The sputum contained many staphylococci, and also the pleural fluid. Is it not so?

DR. HAMPTON: Yes.

DR. BREED: In any event, I am prepared to believe that the staphylococcal infection was not the primary cause of death. There was undoubtedly a superimposed bronchopulmonary infection due to the staphylococcus.

Nothing is stated about the cardiac situation; therefore, I must ignore it. The tourniquets put on the legs suggest some sort of cardiac failure, but I cannot be sure of that.

This question of the sudden appearance of the spleen interests me a great deal; I venture to suggest that it had been present for a long time, and that someone found it one morning.

DR. KING: It was noted in the sanatorium.

DR. BREED: I am glad to hear that because according to the record it appeared during the patient's stay in this hospital. Splens do not appear all of a sudden. Moreover, I question whether

its size really increased in two days. It certainly does not seem reasonable to believe that the spleen had increased in size in a few hours. Therefore I think this man had a chronic disease. On it was superimposed the infection that is here described.

What lead have we concerning the underlying process? If we place emphasis on the leukopenia and the spleen, we might very well consider one of the new growths of the lymphoid series, possibly lymphoma. Having thought of such a possibility, I recalled a case that was somewhat similar to this one in which during life the diagnosis was impossible, and in which the post-mortem examination showed nothing but a peribronchial infiltration by lymphomatous tissue. There were no lymph nodes, and I could never feel the spleen. Whether the patient in the case under discussion had lymphoma or aleukemic leukemia, I do not see how we can do more than guess but I do believe that he had an underlying disease a good while before the month previous to admission. The edema and the sordes and crusts on his nose are not very important except as they indicate a very sick man with malnutrition and riboflavin deficiency.

I have to conclude with the thought that the patient had a lymphoma, a lymphosarcoma or one of the lymphoid series of new growths, with, possibly, some peribronchial infiltration, and that the infection was entirely secondary. Of course, he died of the infection. He would have died of the underlying disease eventually, and it was responsible for the continuing and very bizarre pulmonary infection.

DR. KING: I think you went just far enough. You did a lot better than I thought anyone could possibly do. The patient was sent to the Middlesex County Sanatorium with the diagnosis of pulmonary tuberculosis. He ran a septic temperature, but we could find no evidence of tuberculosis. Many sputum examinations failed to show tubercle bacilli; however, the sputum did show a pure culture of *Staph. aureus*, and the blood culture showed one colony of staphylococcus. We sent the patient into this hospital, thinking that he had staphylococcal pneumonia and septicemia. After his admission here, a chest tap produced a fluid that showed staphylococcus on culture, and I believed that we were dealing with an overwhelming staphylococcal infection. But the course after that made it evident that we were dealing with some unusual condition. No one thought of lymphoma.

DR. BENJAMIN CASTLEMAN: How can you rule out carcinoma?

DR. BREED: I cannot; I forgot to mention the possibility of metastatic carcinoma, which I had considered and discarded because of the leukopenia and the splenomegaly.

DR. HAMPTON: Dr. Lingley and I have been looking at these films, and we agree that the x-ray picture at the first examination looks like that of metastatic neoplasm. I do not know the answer to this case. I noted that the first film was marked tuberculosis, and I erased it before Dr. Breed could see it. I am still going to have my say, however. Later on, the process becomes confluent, like infection, not like metastasis, and the only confluent tumor such as this that I know of is lymphoma. I am therefore inclined to agree with Dr. Breed, especially since Dr. King has complimented his diagnosis.

#### CLINICAL DIAGNOSES

Staphylococcal pneumonia.  
Multiple liver abscesses.

#### DR. BREED'S DIAGNOSES

Lymphoma (? peribronchial).  
Staphylococcal pneumonia, empyema and septicemia.

#### ANATOMICAL DIAGNOSES

Reticulum-cell sarcoma of lungs and kidney.  
Multiple pulmonary infarcts.  
Staphylococcal empyema.  
Septic spleen.  
Thrombophlebitis of femoral veins, bilateral.  
Operative wound: right thoracotomy.

#### PATHOLOGICAL DISCUSSION

DR. MALLORY: We were startled at autopsy by the appearance of the lungs. Both lungs were virtually filled with tumor nodules running from 0.5 to 1 cm. in size. Many showed central necrosis, sometimes with dimpling of the surface, such as one sees with carcinoma. However, they were soft and in that way unlike cancer. There was very little other evidence of tumor. There were a number of slightly enlarged lymph nodes along the aorta, which, however, were not clearly neoplastic. There was, of course, the remnant of staphylococcal empyema, with thick fibrinopurulent exudate in the pleural cavity. One single metastasis about 2.5 cm. in diameter was found in the kidney.

On microscopic examination, it was immediately obvious that this was a lymphomatous tumor, and I should classify it as a reticulum-cell sarcoma. There was not very much peribronchial infiltration, but there was a good deal of perivascular infiltration, with invasion, in many places,

of the arterial walls, and secondary thrombus formation.

So far as the peripheral edema of the legs was concerned, although the serum protein may have played a role, I think it was primarily due to thrombophlebitis of both femoral veins. The spleen was large but not involved by neoplasm. I should have to classify it as a septic spleen.

DR. HAMPTON: Was the intervening pulmonary tissue between the nodules normal?

DR. MALLORY: There was a great deal of tumor not all of which was limited to the sharply outlined nodules seen on gross examination. There was also vaguely outlined infarction; most of it was in tumor tissue, but some was not. This infarction, I think, was due largely to local thrombosis rather than to embolism dependent on direct invasion of the pulmonary arteries by tumor.

DR. HAMPTON: There was no edema?

DR. MALLORY: There was some, but not a great deal.

#### CASE 27472

#### PRESENTATION OF CASE

A fifty-eight-year-old housewife was admitted to the hospital for treatment of a fracture of her right thigh.

She had been seen in the hospital twelve times before, over a period of seven years, because of rheumatoid arthritis involving definitely the fingers, wrists, elbows, shoulders, feet and ankles, and involving questionably the knees, hips and spine. Following her twelfth hospital stay, her joints had appeared to improve, with some restoration of function. The only evidence of active disease was constant elevation of the sedimentation rate. The night preceding her final entry, she slipped from the edge of a bed on which she had been sitting, and fell to the floor, fracturing her right thigh above the knee.

On examination, the patient displayed the same hypertrophic changes of joints as had characterized her arthritis on earlier admissions, except for some progression of the disease in the right shoulder. There was a simple fracture of the right femur, above the knee. The heart, lungs and abdomen were essentially normal.

The temperature was 98°F., the pulse 108, and the respirations 20. The blood pressure was 140 systolic, 70 diastolic.

Examination of the blood at the time of the twelfth admission five months previously had shown a red-cell count of 4,880,000 with 16.1 gm. hemoglobin and a white-cell count of 11,400 with 74 per cent polymorphonuclears. The sedimen-

tation rate was 17 mm per minute Examination of the urine was negative

A roentgenogram of the right thigh showed a comminuted fracture of the lower end of the femur, about 25 cm above the condyles, with the fragments in excellent position

The fracture was treated at first by suspension with traction, and later by application of a plaster cast At the end of the seventh hospital week, the cast was removed and a splint applied to permit exercise A roentgenogram at this time showed a small amount of callus, the fracture lines still remaining distinct The patient received physiotherapy treatments, including the Hubbard tub, but continued to lack muscle strength After four months, active exercise was begun

A month later, in her thirty fifth week in the hospital, she spent a restless night and vomited without apparent cause The next day, she was incontinent of urine and remained in stupor from which she could be roused There was slight weakness of the left eyelid and left side of the face, and the tongue deviated slightly to the left The patient was able to move all her extremities, and there was no loss of sensation The tendon reflexes were hyperactive and equal The plantar responses were equivocal Speech was distinct, without aphasia or inco-ordination The temperature, pulse and respirations remained normal The blood pressure was 150 systolic 95 diastolic The next day, the patient was drowsy, but otherwise seemed normal

Nine days after the onset of this attack, the patient again became drowsy She had been complaining of frontal headache, "like the pressure of a telephone operator's headset" The next day, her stupor became deeper and she responded only to painful stimuli Her lips were cyanotic, her eyelids retracted, and the right eye deviated to the left The pupils were equal and responded to light The fundi appeared normal The deep reflexes were active and equal The plantar reflexes showed withdrawal reactions The right side of the face seemed more relaxed than the left There were no abnormal signs in the chest or abdomen The blood pressure was 150 systolic, 90 diastolic During the next four days, the temperature, pulse and respirations rose gradually, reaching terminal levels of 106.4°F, 160 and 48, respectively Death occurred at the end of the thirty seventh hospital week, following several right sided convulsive movements

#### DIFFERENTIAL DIAGNOSIS

DR MAURICE FREMONT-SMITH I approach this case without my usual confidence that I have a

chance of getting something right Perhaps some of the observations were not correct, certainly, there are very large gaps in the information given us I should like very much to throw the case open to interruptions from the floor,—especially since I see three neurologists sitting here,—because I am sure that I cannot make a very satisfactory discussion

In the first place, the patient was admitted without apparently much the matter with her, except that she had a great deal of some sort of arthritis She fractured her leg, was appropriately treated, and progressed satisfactorily for many weeks Then, one night, she developed restlessness, vomiting and, the next day, stupor and cranial nerve paralysis, she undoubtedly died from an intracerebral accident of some sort Is there very much to help us in making a diagnosis? The patient had rheumatoid arthritis—she had been in the hospital twelve times previously, and that had been the diagnosis On the other hand, we have the statement in the third paragraph that she displayed the same hypertrophic changes of the joints as had characterized her arthritis on earlier admissions That must be, I think, a misprint, or else she did have hypertrophic changes along with the underlying rheumatoid arthritis There was not very much to indicate that the rheumatoid arthritis was still active, except the sedimentation rate, which is good evidence It should be pointed out, however, that a sedimentation rate can sometimes get us off the track Dr J Burns Amberson, Jr, yesterday at the New England Postgraduate Assembly, pointed out the difficulty in recognizing tuberculosis in the age groups from fifteen to twenty two Tuberculosis can go on in a few weeks to rapid involvement of the whole lung and to death, and yet in the early stages there is no cough, no temperature, no rise of pulse and no increase in sedimentation rate—nothing except films that show the disease One cannot therefore eliminate active infection on the basis of a normal sedimentation rate There are, moreover, and I throw this open for discussion, some older people of sixty five or so who have high sedimentation rates—really high I have followed several of them for years, I do not know what is causing the high sedimentation rate, which occurs without anemia and without the development of any disease However, this patient had a high sedimentation rate, and we may accept the fact that she had active atrophic arthritis but I cannot see any connection myself between this and her death Perhaps there is a connection I shall be glad to have remarks from authorities

The only statement we have about the broken leg is that at the end of the seventh hospital week the x-ray films showed a small amount of callus and the fracture lines were distinct. I asked one of the surgical men what he would expect x-ray study to show at the end of the seventh week. He said that he would expect to see a little callus and a fracture line; consequently that is apparently normal healing of the bone. If the patient had had faulty union, one could speculate on the causes of delayed union. She had a fracture, and physiotherapy was given. The Hubbard tub, I am sure, is important, but I do not know why. Then exercises were begun, and a month later she had an episode. It seems to me that this episode, which undoubtedly was some sort of cerebral accident, was entirely independent of anything that had gone before. The patient was in the hospital and had a cerebral accident. That is all I can say. She did not have fat embolus, which comes at the time of fracture and causes collapse. That is out unless there is something abnormal about the fracture. Do we have the x-ray films?

DR. TRACY B. MALLORY: Unfortunately, they were lost.

DR. FREMONT-SMITH: I was sure of it. I knew it as I read the case. If it were a pathological fracture, and if union had been delayed, and it apparently was not, I could discuss with interest the possibility of metastasis, but so far as I can see that is bringing it in by the heels. There is no reason to do so, but there is no reason to bring in anything else either. There is no focus to give emboli, no hypertension. The patient had a good blood pressure for her age. She did not have nephritis, with the possibility of injury to the blood vessels. I should like to tie up the arthritis with her death, but I do not know of any reason to connect it with a vascular accident in any part of the body or brain.

DR. WALTER BAUER: If it is of any help to you, I might add that the patient was older than the stated age.

DR. FREMONT-SMITH: That does help a little bit. Something might have happened more easily.

DR. BAUER: That she had severe rheumatoid arthritis and marked secondary degenerative joints, which developed subsequently, there can be no doubt. She was bedridden when I first saw her and had about decided to remain so the rest of her life. It was only by persuasion and the help of a good strict nurse that she was finally able to walk with a cane and lead an independent life.

DR. FREMONT-SMITH: Although there is no evi-

dence for it, when I first saw the record I thought of coronary disease because it seems to me that there is a connection between rheumatoid arthritis and disease of the coronary arteries; but that does not help explain the cerebral accident. In a woman like this it is possible that emboli arose from a vein. But one would have to assume that the embolus went through the lung, or through a patent foramen ovale, either of which is improbable. We have no evidence. The heart was normal. There is nothing to help us. All we can do is discuss the various possibilities of a lesion that would cause such symptoms as these.

I thought first of metastatic disease—I do not know from where. I thought of vascular disease, and one can also pull some other things out of the air. One could think of marked hypoglycemia, which could cause coma and evidence of organic nerve changes, such as the Babinski reflex, but would not be fatal; there is no reason, however, to consider it. One can list brain tumor or brain abscess, but there is no reason to think of one more than another, except that the patient was old and vascular injury was more likely.

Granting that something happened, where did it happen? I pause specifically for help from the neurologists. How can a lesion cause coma and involve some of the cranial nerves—therefore, probably down around the area of the pons—without involving the pyramidal tract? They are careful to tell us that there was no hemiplegia. There is no information about Babinski signs except that they were equivocal. The patient had lesions that involved first one side and then the other. She probably had multiple basal lesions on the right, but how could they be in that region without involving the pyramidal tract? She did have a convulsion at the end, which theoretically suggests subcortical irritation, but any grave cerebral accident can result in convulsions. This convulsion, however, was right-sided. One would accordingly think of something in the left subcortical region. I have not spoken about subarachnoid hemorrhage, which I think is a possibility, although we are not told whether the neck was stiff. We have little information about the headache. Again, it is very hard for me to see why there was not more involvement of the nervous system if subarachnoid hemorrhage were present. I shall say, before closing the case, that if anyone does know it would be interesting to have more comment and more speculation on the neurologic situation.

DR. MALLORY: No lumbar puncture was done,

and that puts the neurologist at a great disadvantage.

DR. FREMONT-SMITH: No harder for him than for me!

DR. BAUER: There was a very good reason for not doing a lumbar puncture. This patient was between sixty-five and seventy years of age, rather than fifty-eight. We were quite certain that she was going to die. Furthermore, we knew that a post-mortem examination would be granted and that the cause of the cerebral symptoms would probably be ascertained at that time. Therefore, I did not think it necessary to do a lumbar puncture. Perhaps it should have been done for the benefit of this conference.

A PHYSICIAN: Would Dr. Fremont-Smith think of multiple lesions as a cause of the vagueness of signs?

DR. FREMONT-SMITH: I think that there must have been more than one lesion, and I should like a little comment from someone.

DR. MALLORY: Your preference is for a vascular lesion?

DR. FREMONT-SMITH: I should think so in a woman of this age.

DR. BAUER: What type of lesion?

DR. FREMONT-SMITH: I do not know.

DR. CHARLES S. KUBIK: There was drooping of the left upper eyelid. There was no difference in the size of the pupils.

DR. MALLORY: I should be inclined to vote against a vascular lesion. The patient had a very gradual deepening of symptoms, whereas most vascular lesions come on suddenly and then tend to improve. This showed the reverse.

DR. JAMES B. AYER: There is no explanation for the fever except on a neurologic basis?

DR. BAUER: No; not that we could find. It is only fair to say that the lungs were not examined posteriorly the last day or two.

DR. AYER: This case does not conform to vascular thrombosis; we lack the signs of bilateral cortical deficiency from thrombosis on both sides of the brain; and also we fail to have the findings of basilar-artery thrombosis.

Attention to the Hubbard tub is probably due to the fact that the hospital has recently acquired this useful article.

DR. BAUER: Since the patient had rheumatoid arthritis involving the right knee and a fracture of the right thigh, the treatment of which required a long period of immobilization, fibrous-tissue ankylosis occurred. I hated to think that this needed to be permanent. Therefore, she was treated in the Hubbard tub, in the hope that

we could prevent complete loss of motion of the right knee.

DR. MALLORY: Do you want to go ahead and tell us more about it?

DR. BAUER: We proceeded along much the same line of reasoning as Dr. Fremont-Smith did. Because of the sudden onset of headache, I first considered a subdural hematoma. As I saw the patient subsequently, I wondered if she might have multiple cerebral thromboses, a diagnosis that was not confirmed. I have forgotten what my final diagnosis was. I can assure you I was not certain of the exact cause of death.

A PHYSICIAN: Was the convulsion one sided?

DR. BAUER: I do not know. I did not see her at the time it occurred.

DR. MALLORY: The diagnosis was cerebral thrombosis.

## CLINICAL DIAGNOSIS

Cerebral thrombosis.

## DR. FREMONT-SMITH'S DIAGNOSIS

Cerebral lesions due to vascular injury.

## ANATOMICAL DIAGNOSES

Subdural hematoma, left, cerebral.

Rheumatoid arthritis, chronic.

Operative scars: left coracoid osteotomy; cholecystostomy; cholecystectomy; and appendectomy.

Fracture of right femur, old.

Peritonitis, healed, fibrous.

Pleuritis, healed apical, left.

Pulmonary edema, moderate.

Arteriosclerosis: coronary, moderate; aortic, minimal.

Leiomyoma uteri, with calcification.

## PATHOLOGICAL DISCUSSION

DR. MALLORY: At post-mortem examination, the significant findings were in the brain. There was, of course, generalized rheumatoid arthritis and a moderate amount of arteriosclerosis of the aorta and a slight amount of the coronary arteries, but nothing that should have functionally impaired the heart.

Dr. Kubik will tell us the interesting points in the brain.

DR. KUBIK: The finding of drooping of the left upper lid was probably significant. One might have expected an inequality of the pupils and dilatation of the left pupil as well. The lesion was a subdural hematoma on the left side, a fairly large one, surrounded by a rather thin membrane. It did not look as if it were old, and I should not

suppose that it resulted from the fall out of bed several months before death. I do not believe we have any indication of why this occurred. There was characteristic flattening of the frontal lobe by the hematoma, and slight displacement of the midline structures to the opposite side. There was actually some herniation of the medial surface of the hemisphere beneath the falx, a good deal of herniation of the cerebellum into the foramen magnum and slight herniation of the hippocampal gyri into the notch of the tentorium.

DR. FREMONT-SMITH: Should not the disks have been choked?

DR. KUBIK: They usually are not with subdural hematoma, and I should not expect them to be in a case of short duration.

DR. FREMONT-SMITH: Is not a spontaneous affair much more likely to be subarachnoid than subdural?

DR. KUBIK: Yes.

DR. BAUER: The patient had no stiffness of the neck. One would expect a higher temperature with a subarachnoid hemorrhage. These and other findings kept us from making this diagnosis.

DR. MALLORY: Can you see anything in retrospect that should have made one more suspicious of subdural hemorrhage?

DR. KUBIK: No; I do not.

DR. BAUER: After seeing the autopsy, I thought it was much more likely a spontaneous hemorrhage.

DR. KUBIK: I do not believe that it could have been due to the injury nine weeks before.

DR. BAUER: I think it is fair to say that the patient was not quite herself after the accident. She had nausea, vomiting and drowsiness, but there was no mention of headache.

SUBSCRIPTION TERMS: \$6.00 per year in advance, postage paid for the United States; Canada, \$7.04 per year; Boston funds, \$8.52 per year for all foreign countries belonging to the Postal Union.

MATERIAL for early publication should be received not later than noon on Friday.

THE JOURNAL does not hold itself responsible for statements made by any contributor.

COMMUNICATIONS should be addressed to the *New England Journal of Medicine*, 8 Fenway, Boston, Massachusetts.

## ACCURATE BOOKKEEPING RECORDS OF HUMANITY

THE Bureau of the Census refers to the vital statistics of births and deaths as "accurate bookkeeping records of humanity," and the term is not overdramatized since on these data are based such figures as life-expectancy tables, population estimates, information on migration and fertility, and public health trends. The chief responsibility for accurate records rests on physicians, since 90 per cent of the births and deaths in the United States are attended by them. The officials charged with recording these data find it necessary each week to return many certificates, particularly those reporting deaths, because of the inaccuracy and vague phraseology employed.

A uniform vital statistics act was recommended

to the several states in 1939, but there is no guarantee that it will be adopted without change. Some form of registration procedure is required in every state, but the provisions vary to an amazing extent. Maine, in 1821, was the first state to pass legislation requiring registration, and Massachusetts followed in 1840; and complete records for births and deaths since 1848 are available in New Jersey.

The Department of Commerce, through the Bureau of the Census, publishes a pamphlet\* which contains the "International List of Causes of Death" and the additional information that every physician needs to know before he can execute a certificate correctly. Much of the confusion and discussion occurring in medicolegal situations could be decreased or eliminated if this or a similar reference were consulted and used. This is particularly true of those who are removed in point of time or distance from centers of medical education, the physicians in contact with hospitals and teaching services being more meticulous in their use of medical terminology.

The changing nature of our social concepts requires more frequent reference to birth and death certificates, and the physician has a dual obligation—to give more thought to the law and to his patient or the family, particularly to the latter. If he has familiarized himself with the case, he need not find difficulty in being specific. The certificate is of a confidential nature, and no physician should hesitate to indicate a disease such as chronic alcoholism if he is convinced that it is the principal cause of death. The contributory causes—those "which contribute to the risk of dying"—apply to minor underlying or accompanying conditions, including the use of alcohol and drugs. If there is doubt in the physician's mind about the actual role of any factor, a discussion of the case with the proper medicolegal officer may save much embarrassment and time for himself, the relatives and, in certain cases, the courts. If general terms must be used, they should be accompanied and linked with an

\*Physicians' Handbook on Birth and Death Registration. 94 pp. Washington: U. S. Government Printing Office, 1939. This can be obtained from the Superintendent of Documents, Washington, D. C., at a cost of 15 cents.

anatomic site. Medical terms which include the names of men should be avoided. Thus, exophthalmic goiter is preferable to Basedow's or Graves's disease.

The registration of vital statistics is maintained by city, state and federal agencies at considerable expense, and as a matter of economy alone, the basic material should be as carefully presented to the officials charged with registration as is a prescription to an apothecary.

## GRANTS FOR THE STUDY OF POLIOMYELITIS

THE National Foundation for Infantile Paralysis has awarded new grants totaling \$195,030 for research on the etiology, treatment and prevention of poliomyelitis, it was recently announced by Basil O'Connor, president of the foundation.

The objects of the foundation—the control and eventual eradication of the disease and the proper care of those afflicted—can be attained only by study of the virus, the exact nature of which is still unknown, of the most effective therapy and of the character and amelioration of the permanent consequences.

Of the twenty-eight grants made to achieve these purposes, three are of particular interest to physicians in Massachusetts. Two awards totaling \$6300 have been bestowed on the Children's Hospital in Boston to continue the study of the effects of infantile paralysis on the lower extremities and to inaugurate research to determine the effects of prolonged bed rest and other factors in the development of calculi or stones in the urinary tracts of patients with the disease. The Massachusetts General Hospital has received \$2500 to continue the study of clinical cases of infantile paralysis in which the patients have an unequal growth of the lower extremities. A study of the gastrointestinal tract as the portal of entry of the virus has been made possible by a grant of \$3000 to the Boston City Hospital.

The splendid work of the National Foundation for Infantile Paralysis merits the support of the medical profession and the laity. *The courage and*

zeal of the foundation in carrying on its relentless fight against a dreaded disease are an inspiration and a challenge to those who struggle against other diseases that threaten life and health.

## MEDICAL EPONYM

### LANE'S KINK

W. Arbuthnot Lane (b. 1856), surgeon to Guy's Hospital, London, first described this condition in an article, entitled "Chronic Constipation: A consideration of its surgical treatment," which appeared in *Surgery, Gynecology and Obstetrics* (6: 115-129, 1908).

... There can be no doubt that the pathological changes which are present in these conditions of imperfect drainage are most obvious and important. . . . The portion of the caecum above the brim of the pelvis, together with the ascending colon, is retained in a position of abnormal fixity to the posterior wall of the abdomen. This is affected [*sic*] by the development of adhesions between the outer aspect of the large bowel and the peritoneum covering the abdominal wall in its vicinity. . . . As a rule these adhesions merely fix the bowel, but occasionally they constrict its lumen very materially in one or more situations and render it liable to become obstructed. Not only do the adhesions anchor this part of the large bowel, but they also bind down to the iliac fossa a proportion of the appendix. . . . The result of this arrangement is that, when the caecum is loaded, it exerts a vertical strain upon the proximal portion of the appendix and causes that structure to become flexed abruptly at the lower limit of its adhesions. . . . When I recognise that the mechanics of the intestines have been altered to a degree that cannot be rectified satisfactorily by the division of bands, etc., I divide the ileum at a distance of about five or six inches from the caecum, . . . the descending colon and sigmoid are removed, the rectum . . . being occluded in the same manner as the ileum.

### SECTION OF OBSTETRICS AND GYNECOLOGY\*

#### SPONTANEOUS, INCOMPLETE ABORTION, FOLLOWED BY FATAL HEMORRHAGE

A twenty-eight-year-old para II was not seen until she was referred to the hospital by a physician who had been called by the patient because she was flowing.

The past history was irrelevant. Physical examination on admission was normal. The patient

\*A series of selected case histories by members of the section will be published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the section. Letters should be addressed to Dr. Raymond S. Titus, Secretary, 330 Dartmouth Street, Boston.

was about three months pregnant, and was bleeding very freely. The pulse ranged from 120 to 140, and she was in some degree of shock.

The first step in treatment was a transfusion of 600 cc. of citrated blood. Then, the patient was examined vaginally. The placenta, which was found lying in the cervix, was removed, and the uterus packed. Since the patient continued to bleed, the pack was removed, and the uterus examined for retained pieces of tissue; none were found. In spite of the transfusion and stimulants, the patient died.

*Comment.* This is a case of spontaneous incomplete abortion associated with fatal hemorrhage. Massive hemorrhage from abortion is rarely seen before the twelfth week. Not infrequently, however, a patient with an incomplete abortion may start bleeding at six or eight weeks and continue to bleed freely off and on, which eventually results in a hemoglobin below 50 per cent and a correspondingly low red-cell count; such patients seldom bleed to the point of exsanguination.

Since it is reported that there were no products of conception left in the uterus in this case, the absence of contractility of the uterus must have been due to the lack of muscular tone that is associated with the shock that accompanies so many of these large hemorrhages. Everything possible seems to have been done for this patient. The record does not say that the patient had been bleeding off and on before the hemorrhage was alarming enough to cause her to seek medical advice. If this had occurred and if the patient had been under medical observation, with no attempt to investigate the cause of bleeding, the medical attendant might well have been criticized.

## DEATH

STOODLEY—HARRY M. STOODLEY, M.D., of Somerville, died November 5. He was in his sixty-fourth year. Born in Charlestown, Dr. Stoodley received his degree from Tufts College Medical School in 1904. He was a former member of the Massachusetts Medical Society. He is survived by his widow, two sons and a sister.

## CORRESPONDENCE

### NURSE-MIDWIVES

*To the Editor:* I was greatly interested in your editorial in the August 21 issue of the *Journal*, entitled "Maternal Welfare and the National Emergency," in which the use of the trained nurse-midwife in solving some of our problems of maternal care is suggested.

The Community Health Association, as you know, is the visiting nurse association for the City of Boston—a private agency dependent largely on the Greater Boston Community Fund for its support. In our nursing program, care of maternity patients is one of the biggest

services. Last year, for instance, over 8000 prenatal cases in the city were registered with us for nursing care and supervision. This includes care during the prenatal period, assisting the physician at the time of delivery if the mother is delivered at home, and care to mother and baby during the post-partum period. If the mother is delivered in the hospital, the nurse makes one or two visits after she returns home with her baby, to demonstrate the baby's bath and instruct the mother.

While the majority of maternity patients in Boston are delivered in hospitals at the present time, there are still a goodly number who remain at home under the care of a private physician or of one of the out-door delivery services conducted by the teaching hospitals. It is the policy of our association to give nursing supervision to prenatal cases only when they are registered with a physician or clinic, and we have always had excellent working relations with both private physicians and clinics.

In spite of this seemingly adequate maternity program in the City of Boston, we realize that there are still many maternity patients who go without prenatal supervision and only seek medical care when labor starts. Our nurses are constantly on the alert in their general nursing program to find these patients and to urge them to get under medical care. Even so, there are many that elude us.

Do you feel that there is a place in Boston for the nurse-midwife? Should we be urging some of our well-prepared nurses to secure this training and go into this field of service?

DOROTHY J. CARTER, *General Director*

Community Health Association  
Boston

\* \* \*

No one will deny that the care of maternity cases, particularly in Boston, owing in part to the efforts of the Community Health Association, has been markedly bettered in the last ten or fifteen years. The fact remains, however, as brought out in the editorial and acknowledged by Miss Carter, that many cases do not receive proper, if any, attention. Furthermore, in the event of mobilization, it is obvious that even more mothers would receive inadequate medical care. The editorial suggested that the possibility of utilizing, with rigid supervision, the trained nurse-midwife in crowded tenement districts and in sparsely settled rural communities—a practice now prohibited by Massachusetts statutes—be given due consideration. Ed.

### PREMARITAL MEDICAL EXAMINATIONS

*To the Editor:* The Massachusetts premarital health-examination law has been amended so that physicians on active service in the armed forces of the United States may make the required examination.

For this purpose the Department of Public Health has approved all serologic laboratories of the United States Army, Navy and Public Health Service and all laboratories operated by state health departments and by the District of Columbia. All other physicians practicing in Massachusetts must send the blood specimen for serologic examination for syphilis to an approved laboratory in Massachusetts.

A further amendment requires that the department furnish blank forms of certificates required under the act to city and town clerks.

PAUL J. JAKMAU, M.D.  
*Commissioner of Public Health*

State House  
Boston

## BOOK REVIEWS

*Biological Symposia*. Vol. I. *The Cell Theory; Mating Types and Their Interactions in the Ciliate Infusoria; Chromosome Structure*. Edited by Jaques Cattell. With a foreword by Albert F. Blakeslee, Ph.D. 4°, cloth, 238 pp., with 39 illustrations and 19 tables. Lancaster, Pennsylvania: The Jaques Cattell Press, 1940. \$2.50.

The Jaques Cattell Press is to be congratulated in making permanent the biological symposiums held at the Richmond meeting of the American Association for the Advancement of Science. These symposiums present the latest authoritative information in the various fields of biology. A good idea of the subject matter covered may best be obtained by listing the subjects discussed and the experts who participated in them.

The first symposium was on the cell theory; Dr. Joseph Mayer was chairman. The papers presented were: "The Cell Theory: Its past, present and future," by Dr. Joseph Mayer; "Microscopy before the Nineteenth Century," by Professor Lorange L. Woodruff; "Schleiden's Contribution to the Cell Theory," by Professor John S. Karling; "Predecessors of Schleiden and Schwann," by Professor Edwin G. Conklin; "A Modern Concept of the Cell as a Structural Unit," by Professor George A. Baitsell; "The Present Status of Mitosis," by Professor Franz Schrader; "The Problem of Cell Individuality in Development," by Professor Paul Weiss; "What of the Future?" by Professor Clarence E. McClung.

The second symposium was on mating types and their interactions in the ciliate infusoria; Dr. Herbert S. Jennings was chairman. After an introduction by Dr. Jennings, the topics considered were: "*Paramecium aurelia*," by Dr. Tracy M. Sonneborn; "*Paramecium bursaria*," by Dr. Jennings; "Studies on Conjugation in *Paramecium multimicronucleatum*," by Professor Arthur G. Giese; "Mating Types in *Paramecium caudatum*," by Lauren C. Gilman; "Mating Types in Euplates," by Richard F. Kimball.

The third symposium was on chromosome structure, with Professor Theophilus S. Painter as chairman. The topics considered were: "On Coiling in Chromosomes," by Dr. Bernhard R. Nebel; "The Physicochemical Nature of the Chromosome and the Gene," by Dr. C. H. Waddington; "The Structure of Salivary Gland Chromosomes," by Professor Painter; "Chromosome Structure as Viewed by a Geneticist," by Dr. Millislav Demerec.

*Biological Symposia*. Vol. II. *Speciation; Defense Mechanisms in Plants and Animals; Biological Basis of Social Problems; Regeneration*. Edited by Jaques Cattell. With a foreword by George A. Baitsell, Ph.D. 8°, cloth, 270 pp., with 13 illustrations and 1 table. Lancaster, Pennsylvania: The Jaques Cattell Press, 1941. \$2.50.

The second volume on biological symposiums will excite the interest of all students concerned with the phenomena of life.

The topics dealt with in the first symposium were: "Introduction," by Dr. Leon J. Cole; "Speciation of Fishes," by Dr. Carl L. Hubbs; "Ecologic and Genetic Variability within Species of *Peromyscus*," by Dr. Lee R. Dice; "Speciation from the Point of View of Genetics," by Dr. M. R. Irwin and Dr. R. W. Cumley; "Breeding Structures of Populations in Relation to Speciation," by Professor Sewall Wright; "Speciation Phenomena in Birds," by Dr. Ernst Mayr; "Speciation in *Peromyscus*," by Dr. Lee R. Dice; "Levels of Divergence in *Drosophila* Speciation," by Professor Warren P. Spencer; "Speciation

as a Stage in Evolutionary Divergence," by Professor Theodosius Dobzhansky.

The second symposium, on the topic of defense mechanisms in plants and animals, comprised: "Local Reactions in Plants," by Dr. Fritz W. Went; "Generalized Defense Reactions in Plants," by Dr. W. C. Price; "Local and Generalized Defense Reactions in Animals," by Dr. William Bloom.

The third symposium, on the biological basis of social problems, was composed of the following: "Introduction," by Dr. Samuel J. Holmes; "A Few Words About Nature," by Dr. William E. Ritter; "Social Integration as a Biological Process," by Professor Charles M. Child; "The Naturalist as a Social Phenomenon," by Dr. Francis B. Sumner; "The Ethics of Enmity in Social Evolution," by Professor Holmes; "A Biologist's Appreciation of Religion as a Factor in Social Evolution," by Dr. Edwin B. Copeland.

The fourth symposium, concerning regeneration, contained the following papers: "Introduction," by Professor J. William Buchanan; "The Histologic Basis of Regeneration and Reassociation in Lower Invertebrates," by Dr. Winterton C. Curtis; "The Environmental Control of Regeneration in Euplanaria," by Dr. Olin Rulon; "Aspects of Regeneration in Annelids," by Dr. Libbie H. Hyman; "Contributions to the Problem of Regeneration in Protozoa," by Dr. William Balamuth.

## NOTICES

## MASSACHUSETTS GENERAL HOSPITAL

A meeting of the Hospital Research Council will be held in the Bigelow Amphitheater of the White Building on Tuesday, November 25, at 5 p.m.

## PROGRAM

Effect of the Serum of Patients with Graves's Disease, Myxedema and Acromegaly on the Oxygen Consumption of Guinea-Pig Thyroid. Dr. Carlos Galli-Mainini.

Chemotherapy of Experimental Staphylococcal Infections. Dr. Champ Lyons.

Retardation of Epiphyseal Growth by Roentgen Irradiation. Drs. J. S. Barr, E. A. Gall and J. R. Lingley.

Further Studies on the Optimal Solution for the Dissolution of Calcium Phosphate Calculi. Drs. Fuller Albright, R. Murdoch, H. Suby and H. Sulka-witch.

## JEWISH MEMORIAL HOSPITAL

A diagnostic and therapeutic conference will be held at the Jewish Memorial Hospital on Thursday, November 27, at 11 a.m. Dr. J. H. Swartz will speak on "Diseases of the Skin."

Physicians and medical students are invited to attend.

## NEW ENGLAND PATHOLOGICAL SOCIETY

A meeting of the New England Pathological Society will be held at the Peter Bent Brigham Hospital on Thursday, November 27, at 8 p.m. Dr. William Dock, professor of pathology at Cornell University Medical College, will speak on "The Kidney and Hypertension."

Physicians and medical students are cordially invited.

## MILITARY SYMPOSIUM

### FATIGUE IN AIRCRAFT PILOTS\*

Ross A. McFarland, Ph.D.†

BOSTON

ONE of the most significant problems in civil and military aviation relates to what is popularly known as "pilot fatigue." Conclusions about its nature or even its locus, however, are almost as numerous as the articles that have been written, since each depends largely on the interests or background of the author. Viteles<sup>1</sup> says that the word "fatigue" used both popularly and scientifically refers to three related phenomena: 'An over manifestation in the form of reduced output on the task known as work decrement, a physiological state involving changes in organic functions and the production of chemical products of fatigue, and a feeling of fatigue or tiredness.' Schneider<sup>2</sup> suggests that it 'is a progressive flagging of efficiency, together with subjective sensations of loss of control.' Grow<sup>3</sup> has advanced the hypothesis, based on wide experience in the field of aviation, that "fatigue is due to the excessive generation of nerve impulses and originates in the nervous tissue of the body."

The varieties of interpretation may be due in part to the fact that the word "fatigue" does not have a specific meaning in a scientific sense. It refers, generally speaking, to a related group of phenomena associated with loss of efficiency. In common usage, it is not unlike the word "unconscious" in psychopathology—a convenient category used to classify certain phenomena that are essentially unknown or not clearly understood, yet nonetheless real. The problem cannot be explained away, however, simply because agreement cannot be obtained relative to the phenomenon itself, its nature or its locus. In a practical sense, everyone, particularly a pilot after a long flight over difficult terrain and in adverse weather conditions, understands in a subjective

sense what is meant by the words "nervous and physical exhaustion" and "fatigue."

In this discussion, an attempt to be practical is made, since the flight surgeon is always faced with practical problems. An operations' manager or flight officer, for example, may approach him with such questions as these: The pilots on certain routine operations are returning to their bases completely exhausted, is the flying time too long? Do they fly at too high altitudes without oxygen? Or is there something in the cockpit that affects them adversely, such as vibration, noise or poor illumination? Or, again, Captain Jones does not seem to be himself these days. He has "gone stale." He is tense, nervous and irritable, and shows poor judgment in making decisions while in flight. He used to be one of the ablest pilots in the flight group, but his flying is no longer trusted. Should he be grounded or sent away on a vacation? Finally, in the daily press are recorded accidents attributed to "pilot error." In the early stages of the war, the British pilots were evidently losing more planes in landing accidents on returning home from fighting abroad than during actual combat with the enemy. In civil aviation in this country, a large percentage of the accidents (often estimated at 80 to 90 per cent) are ascribed to pilot error. Do these pilots become so exhausted that their judgment is faulty when they make decisions or land? Do latent or minor visual defects in acuity, in night vision, in space perception and in sensory motor performance become manifest or acute after long hours of fighting under intense emotional strain?

Since one cannot control and measure all the variables involved, the answers to such questions are indeed difficult. In a short discussion, one can hope to indicate only some of the more important contributing factors involved in pilot fatigue. Only brief mention is made, therefore, of the so-called "locus" of fatigue and of the accumulation of

\*This and the three subsequent papers were presented as part of a symposium at the annual meeting of the Massachusetts Medical Society, Boston, May 22, 1941.

†Assistant professor of industrial research, Harvard University; consultant Pan American Airways System.

fatigue substances. Emphasis is placed on the variations in energy resources, such as oxygen and sugar, and, more especially, on several major contributing factors to fatigue, such as worry, personal maladjustments, lack of exercise, the effects of high altitude, poor selection of food, the excessive use of alcohol and tobacco, and certain factors in the cockpit of an airplane, such as noise and vibration. Finally, a study of fatigue in transoceanic airmen is discussed.

### *Locus of Fatigue*

For many years, physiologists have attempted to locate fatigue in certain parts of the body—in the muscle itself, the nerve end plate, the nerve fiber, the synaptic junctions or the cortical cells of the brain. Numerous experiments have shown that the nerve fiber is almost indefatigable. These phenomena are demonstrated to students of physiology with the classic experiment involving a nerve-muscle preparation. A frog muscle, with its efferent nerves, is isolated; the nerve is stimulated until the muscle ceases to contract. Then, if the muscle is stimulated directly, it may react almost as vigorously as before. If the nerve is given a normal supply of oxygen and stimulated alone, it will continue to transmit impulses more or less indefinitely. By such procedures, attempts have been made to demonstrate the relative efficiency of the nerve and muscle and the possible location of fatigue in the nerve end plate or the synapses.<sup>4</sup> Although one can demonstrate that certain muscles are subject to loss of efficiency in ergographic studies, this sheds little light on the fatigue problem in aviation, in which the pilot's gross musculature is not used excessively. Studies of isolated nerve fibers have proved to be equally inconclusive concerning the basis of fatigue. Except for the role of oxidation in the efficient functioning of the nerve tissue, therefore, the implications of these experiments for pilot fatigue are not very direct.

It may be that the psychologists who have stressed the role of the higher cortical levels have more information to offer regarding pilot fatigue. They speak of mental "blocking," and they have demonstrated that, under certain conditions involving stress, there is a loss of efficiency in mental tasks.<sup>5</sup> This is especially true of the tasks that involve the more complex cortical functions, such as memory and delicate judgments of discrimination and choice.

In the field of vision, in which the processes involved are concerned essentially with minute muscle or nervous tissue, objective data on visual fatigue are very inadequate and inconclusive. Many

authorities believe that the frequency with which ocular defects are observed in children (often estimated at 40 per cent) and in adults is directly related to the various strains imposed on the eyes in modern life. Unfortunately, however, little is known about the basic causes of these abnormalities or of the contributing factors to visual discomfort or loss of efficiency in visual work. Even in an applied problem in industry, such as the amount of illumination necessary to prevent visual discomfort, one finds a wide divergence of opinion among equally prominent authorities. The problem is complicated by the nature of the visual mechanism itself—that is, the retina is an extremely complex organ, being essentially an extension of the brain. It involves only a small amount of tissue, it adapts itself readily to changes in the environmental setting, and it apparently recuperates rapidly from ordinary stresses. In fact, many believe that the retina is indefatigable. Experiments dealing with the ocular muscles used in reading show that they are not easily subject to a work decrement. Carmichael and Dearborn<sup>6</sup> have failed, for example, to find evidence of fatigue of the muscles of the eye during six hours of continuous reading. The records were made by attaching electrodes to each side of the eye so as to record the action potentials of the ocular muscles during reading. Although the basis of visual fatigue is not clearly understood, it is essential to protect the pilot from variables known to accentuate visual discomfort, such as excessive glare from the clouds or sun, reflections from metal surfaces on the plane and poor illumination in the cockpit.

### *Accumulation of Toxic Substances*

For many years, physiologists have attempted to associate fatigue with certain substances in the blood. At one time, many believed that lactic acid was the long-sought toxin.<sup>7</sup> Dill and his colleagues<sup>8</sup> have shown that the accumulation of lactic acid is related to fatigue but that, as an explanation of this phenomenon, such accumulation is more restricted than observers at first believed. Their experiments have revealed that the concentration of lactic acid in the blood remains a useful index to the degree of fatigue in one sort of activity, for example, that in which either the oxygen supply is deficient or the oxidative mechanism of the muscles is not competent to meet the demands placed on it. In studying a group of persons varying in athletic fitness or training, they<sup>9</sup> observed that in a famous Marathon runner there was no accumulation of lactic acid. In several untrained subjects, however, the accumulation of

lactic acid was very great. Those who were well trained were able to carry out the tasks with ease, whereas those in poor training who created large amounts of lactic acid were severely handicapped. The magnitude of the increase in lactic acid was closely related to the degree of fatigue, as indicated by other objective measures, such as the heart rate, respiratory rate and blood pressure, and by subjective evidence. That lactic acid is not the only factor was evidenced by the fact that many track records are broken by athletes in successive heats with large amounts of lactate in their blood. Furthermore, industrial workers doing heavy work, as well as miners at high altitudes, have been observed to have normal values for lactate in the blood. Other substances have been proposed as toxic factors in fatigue, such as ammonia and histamine, but further evidence is required to establish these theories.

#### *Exhaustion of Energy Reserves*

A great deal has been written about the exhaustion of such energy reserves as sugar as a causative factor in fatigue. Experiments indicate that in very exhausting work—in a Marathon race or industry—the administration of glucose is of considerable value in maintaining efficiency. In work with a bicycle ergometer, Christensen et al.<sup>10</sup> observed that a very low blood sugar was associated with exhaustion and even sensory impairment. These effects were rapidly counterbalanced by the ingestion of glucose, and the subjects could continue the work for an hour or more. In heavy work, the preferred fuel is carbohydrate. If heavy labor is continued for a long time without food, the diminishing reserve of carbohydrate is associated with a falling respiratory quotient, a reduction in efficiency, a decreasing concentration of blood sugar and the appearance of acetone in the urine. Subjects in poor physical condition have low reserves of energy and a reduced capacity for transforming energy. Unfitted or untrained factory workers, therefore, may benefit from glucose or other readily available fuel taken between meals. They seldom work hard enough to exhaust their stores of sugar and other reserves. The effects are chiefly on the central nervous system. It is difficult to explain the reports of benefits from the ingestion of glucose in more sedentary occupations.<sup>11</sup> During very long and exhausting flights at high altitudes, pilots are benefited by taking such foods as glucose, which is easily assimilated between meals. From evidence obtained on heavy muscular work, however, it is difficult to understand how a pilot could consume his entire carbohydrate reserve, since the amount of gross musculature involved is so small. It appears, there-

fore, that the exhaustion of energy reserves in a pilot could hardly be an important causative factor in fatigue.

In the field of mental work, it is even more difficult to explain how the ingestion of sugar might counteract the effects of fatigue, although it is well known that the nervous system is primarily dependent on carbohydrate for fuel. The metabolic cost of mental work is very slight indeed. Laird's<sup>12</sup> report that fatigue in students doing simple psychomotor tests is modified favorably by the ingestion of certain sugars, such as maltose, has not been confirmed by other workers. In carefully controlled experiments on the metabolic cost of mental work, Benedict<sup>13</sup> found that sustained mental effort for several hours required only the number of calories in half a peanut. Other experiments have shown that in mental work it is not the involvement of the nervous system that increases oxygen consumption, but the musculature and other parts of the body associated with attention and sustained concentration. Hence, the fatigue from mental work is due in part to the increased muscular tonus associated with sustained attention.

In spite of negative findings in studies of mental fatigue everyone is aware that subjectively it is a real phenomenon. Barcroft<sup>14</sup> suggests that mental fatigue, like chronic oxygen want, undermines normal self control, with consequent exaggeration of feelings and mental abnormalities. He recalls that, after prolonged strenuous work during the war, he broke down and cried for no apparent reason, as he did at the termination of his six-day stay in the low-oxygen chamber. It is common for anyone, after prolonged mental effort or continuous overwork, to be aphasic, quick tempered and lacking in self control to a marked extent, quite trifling experiences make one furious. Barcroft intimates that the mentally overworked person who eventually seeks medical or psychiatric advice is possibly suffering from chronic oxygen want. Overexertion breaks down the tissues, owing to insufficient oxygenation, and a prolonged rest is required before adequate restoration can take place. Barcroft concludes that one cannot at present answer one way or the other the question whether mental fatigue is due to oxygen want. The impairment may be caused by a defect in any link in the oxidation process. But one can state with certainty, he avers, that "a given strain produces a greater degree of mental fatigue as it would of muscle fatigue, when the oxygen supply is deficient than when it is ample." This observation is of significance for the pilot whose environment is known to be deficient in oxygen.

fatigue substances. Emphasis is placed on the variations in energy resources, such as oxygen and sugar, and, more especially, on several major contributing factors to fatigue, such as worry, personal maladjustments, lack of exercise, the effects of high altitude, poor selection of food, the excessive use of alcohol and tobacco, and certain factors in the cockpit of an airplane, such as noise and vibration. Finally, a study of fatigue in transoceanic airmen is discussed.

### *Locus of Fatigue*

For many years, physiologists have attempted to locate fatigue in certain parts of the body—in the muscle itself, the nerve end plate, the nerve fiber, the synaptic junctions or the cortical cells of the brain. Numerous experiments have shown that the nerve fiber is almost indefatigable. These phenomena are demonstrated to students of physiology with the classic experiment involving a nerve-muscle preparation. A frog muscle, with its efferent nerves, is isolated; the nerve is stimulated until the muscle ceases to contract. Then, if the muscle is stimulated directly, it may react almost as vigorously as before. If the nerve is given a normal supply of oxygen and stimulated alone, it will continue to transmit impulses more or less indefinitely. By such procedures, attempts have been made to demonstrate the relative efficiency of the nerve and muscle and the possible location of fatigue in the nerve end plate or the synapses.<sup>4</sup> Although one can demonstrate that certain muscles are subject to loss of efficiency in ergographic studies, this sheds little light on the fatigue problem in aviation, in which the pilot's gross musculature is not used excessively. Studies of isolated nerve fibers have proved to be equally inconclusive concerning the basis of fatigue. Except for the role of oxidation in the efficient functioning of the nerve tissue, therefore, the implications of these experiments for pilot fatigue are not very direct.

It may be that the psychologists who have stressed the role of the higher cortical levels have more information to offer regarding pilot fatigue. They speak of mental "blocking," and they have demonstrated that, under certain conditions involving stress, there is a loss of efficiency in mental tasks.<sup>5</sup> This is especially true of the tasks that involve the more complex cortical functions, such as memory and delicate judgments of discrimination and choice.

In the field of vision, in which the processes involved are concerned essentially with minute muscle or nervous tissue, objective data on visual fatigue are very inadequate and inconclusive. Many

authorities believe that the frequency with which ocular defects are observed in children (often estimated at 40 per cent) and in adults is directly related to the various strains imposed on the eyes in modern life. Unfortunately, however, little is known about the basic causes of these abnormalities or of the contributing factors to visual discomfort or loss of efficiency in visual work. Even in an applied problem in industry, such as the amount of illumination necessary to prevent visual discomfort, one finds a wide divergence of opinion among equally prominent authorities. The problem is complicated by the nature of the visual mechanism itself—that is, the retina is an extremely complex organ, being essentially an extension of the brain. It involves only a small amount of tissue, it adapts itself readily to changes in the environmental setting, and it apparently recuperates rapidly from ordinary stresses. In fact, many believe that the retina is indefatigable. Experiments dealing with the ocular muscles used in reading show that they are not easily subject to a work decrement. Carmichael and Dearborn<sup>6</sup> have failed, for example, to find evidence of fatigue of the muscles of the eye during six hours of continuous reading. The records were made by attaching electrodes to each side of the eye so as to record the action potentials of the ocular muscles during reading. Although the basis of visual fatigue is not clearly understood, it is essential to protect the pilot from variables known to accentuate visual discomfort, such as excessive glare from the clouds or sun, reflections from metal surfaces on the plane and poor illumination in the cockpit.

### *Accumulation of Toxic Substances*

For many years, physiologists have attempted to associate fatigue with certain substances in the blood. At one time, many believed that lactic acid was the long-sought toxin.<sup>7</sup> Dill and his colleagues<sup>8</sup> have shown that the accumulation of lactic acid is related to fatigue but that, as an explanation of this phenomenon, such accumulation is more restricted than observers at first believed. Their experiments have revealed that the concentration of lactic acid in the blood remains a useful index to the degree of fatigue in one sort of activity, for example, that in which either the oxygen supply is deficient or the oxidative mechanism of the muscles is not competent to meet the demands placed on it. In studying a group of persons varying in athletic fitness or training, they<sup>9</sup> observed that in a famous Marathon runner there was no accumulation of lactic acid. In several untrained subjects, however, the accumulation of

factors, lack of exercise, the effects of lack of oxygen at high altitude, the wrong kind of diet and the excessive use of alcohol and tobacco are major contributing factors.

### *Exercise and Pilot Fatigue*

The trend of civilization from the earliest times has shown a close relation of the fitness of man and animals to their environment. If the environment changes, the animals must change to meet the new conditions. Airmen, to meet the requirements of prolonged sojourns at high altitude, must therefore attempt to adapt themselves so as to live comfortably and remain efficient under these conditions. In man's fight with the environment, the neuromuscular mechanisms have played a vital role. Under modern urban conditions, the muscles, lung surface and heart tissue are far in excess of what is needed for sedentary life. Unless the extra tissue is called into play, it atrophies and becomes a source of weakness. The highly trained athlete who suddenly stops training after leaving college is especially vulnerable to organ dysfunction. Large parts of the central nervous system are set aside for muscular activity, and this reserve must be used if it is not to become a source of danger.

The increase in emotional and mental disorders may also be related to the very great changes in modern, as compared to primitive, life. The glandular changes known to occur under emotional excitement, such as fear and anger, equip the organism for a struggle.<sup>21</sup> The secretion of adrenaline from the adrenal glands causes the blood pressure and heart rate to increase; the blood is directed from visceral activity to the muscles and brain; there is an increase in the rate and depth of breathing and a dilatation of the bronchioles of the lungs to facilitate the transport of oxygen to the arterial blood; the glycogen stored in the liver is released to provide extra fuel for the muscles; the pupils are dilated; and there is an increased rate in the coagulation of the blood in case of injury. All these changes have great significance in the survival of the organism in the event of a struggle. Under civilized conditions, however, there is less and less opportunity for an overt struggle, and there is less need for these physiologic changes. Continual emotional stress without overt activity may therefore have a cumulative ill effect on the efficiency of the organism in meeting situations involving stress. In piloting an airplane, there may be continual emotional stress, especially in adverse weather and over difficult terrain, without an excessive amount of physical exertion. At the end of the flight, the pilot should

attempt to obtain some form of physical exercise, to keep in condition.

There is some evidence of concrete advantages from routine exercise for airmen. The pilots in the Royal Dutch Airlines apparently derived benefit from routine gymnastics during a week following long flights from the Continent to the Dutch East Indies and return. In a study of 50 Pan American Airways pilots in Miami, Dr. John T. Macdonald<sup>22</sup> observed an increase of four points in the Schneider index by moderate yet routine exercise over a period of several months. The benefits derived from such procedures were especially apparent in the older pilots. Further controlled studies are indicated to demonstrate the value of regular exercise for airmen.

It is a common experience to find that a man in poor physical condition is easily exhausted by mental and physical exertion: he is irritable and likely to have morbid thoughts, petty ailments and poor judgment; he may have a sallow complexion and dull eyes; and he frequently complains of constipation, headache, nervousness and insomnia. On the other hand, it is equally common to observe in a man of good physical condition evidences of mental and bodily vigor, such as alertness, cheerfulness, high morale, healthy complexion and capacity for arduous mental and physical work. It is believed that these two conditions are but the outward expression of physiologic differences within the body. There are no tests available to predict whether a pilot will make a serious error of judgment or lose emotional control in a crucial situation. For the most part, however, it is safe to say that errors of judgment or emotional confusion are the reflection of a poor or rundown physical condition. For this reason, a pilot must maintain a high degree of physical fitness.

### *Effects of Altitude in Accentuating Fatigue*

It is well known that the important reactions in the human organism encountered at high altitude are due to the diminished partial pressure of oxygen.<sup>23</sup> There is no storage of oxygen in the human economy, as there is for other chemical substances like sugar and calcium, although the release of red cells by the spleen and bone marrow may be considered a reserve of oxygen in a limited sense. The blood is really the only storehouse, and its capacity is very limited. Hence, the body lives a hand-to-mouth existence and is dependent on a constant supply from the atmosphere. At 10,000 feet, a given breath of air supplies only two thirds as much oxygen as at sea level, and at 18,000 feet only half as much.

The average unacclimatized passenger is apt

to complain of certain physical discomforts while flying above 10,000 to 12,000 feet. In an extensive investigation carried out in experimental chambers at sea level and during prolonged flights at high altitude, the following reactions have been recorded voluntarily by the subjects and passengers.<sup>24</sup> The list is arranged in order of frequency and severity: slight frontal headache, which may become worse with increasing altitude; dizziness or vertigo on moving suddenly or in stooping over too rapidly; difficulties or irregularity in breathing and shortness of breath on exertion; digestive disturbances, especially gas in the stomach and in the intestines, and indigestion or slight nausea; slight sensory impairment on moving too suddenly, especially noticeable in alterations in vision; a tendency toward sleepiness or lethargy; and a sense of exhaustion and fatigue on exertion.

The response of the average passenger or pilot to high altitude may be influenced by a large number of variables. Since these factors are so essential in determining the altitudes where oxygen should be used and in answering other practical problems in civil aviation, a number of the more important ones are listed below. All these variables are either directly or indirectly related to the problem of pilot fatigue.

*Height attained.* There are great individual differences among the specific altitudes where the effects are first noticeable or become marked. Some persons may be affected at 8000 feet, and others at 16,000 to 18,000 feet. In a group of over 150 unselected subjects varying in age and physical fitness, in low-oxygen chambers at sea level during exposures of two to four hours' duration, the initial effects were significant in the average person at from 10,000 to 12,000 feet.<sup>24</sup> The effects may become quite marked at 14,000 to 16,000 feet and dangerous at 18,000 to 20,000 feet. The upper limit of consciousness in unacclimatized man appears to be about 25,000 feet.

*Rate of ascent.* In a series of experiments on rate of ascent, it was observed that if the high altitude is attained gradually, — that is, in an hour, — the effects are considerably less serious than during an ascent to similar altitudes within fifteen minutes. In a number of subjects who showed very poor responses following rapid ascents to 16,000 feet, a satisfactory acclimatization was made during repeated experiments in which the ascent was extended over one hour and fifteen minutes. During a slow ascent, the mechanisms of adjustment to the reduction in oxygen pressure have an opportunity to function. On the trans-Pacific flights, where from one to three hours may elapse

before the ship is leveled off at the desired altitude, slow ascents are physiologically favorable to the passengers and flight personnel.<sup>25</sup>

*Length of exposure.* Moderate altitudes of 6000 to 10,000 feet may be tolerated over long periods (eight to fourteen hours) without apparent ill effects. This does not seem to be so at 12,000 to 14,000 feet. Although the mechanisms of acclimatization may be effective at moderate altitudes, the opposite appears to be true at higher altitudes. Deterioration may set in, and the physical symptoms during the flight may be quite unpleasant. Older pilots find it advantageous to use oxygen at and above 9000 feet for flights of more than two or three hours' duration.

*Amount of physical exertion.* The effects of high altitude tend to be accentuated during exercise. This is of particular significance in stewards, whose chief activity involves the preparation and serving of meals and making up the berths while in flight. On this account, the other members of the flight crew should not make excessive demands on the steward during flights at high altitudes. Care should be taken not to make too sudden movements or to stoop over too quickly because of cerebral anemia or lack of blood and oxygen in the brain and the increased susceptibility to fainting. Passengers should be urged to remain quietly seated following a meal at high altitude, so that the blood will not be diverted from the digestion of food to the muscles. Also, the airmen might find it advantageous to arrange their meals aloft so as to relax for a short time following a meal before going on duty again.

*Roughness of air and sudden movements of plane.* Air-sickness becomes greatly accentuated at high altitude. Because of the combined effects of oxygen lack and rough air in interfering with the digestion of food, special precautions should be taken in the kinds of food ingested while one is flying under adverse conditions at high altitude.

#### *Importance of Pilot's Diet*

Among the factors that may affect the efficiency of a pilot, no one is more significant than his food. This is especially true during flying, because of the effects of oxygen lack on digestion. Several controlled experiments have been carried out on the effects of reduced oxygen pressure on the digestive processes. In studies with dogs, Delrue<sup>26</sup> observed a marked diminution of gastric secretion, lasting from two to three days, in animals taken from a low to a high altitude. Van Liere, Crisler and Robinson<sup>27</sup> found that the emptying time of the stomach was prolonged in proportion, so that at 20,000 feet the dogs had food

lower his ceiling, just as it would impair his performance in a track or crew race at sea level, owing to the unknown effects on the lungs and circulation. It also impairs his digestive processes and the assimilation of food. The airman is warned against smoking before breakfast and against the excessive inhalation of cigarette smoke at all times.

#### *Effects of Noise and Vibration and Other Variables in the Cockpit*

Certain variables in the cockpit of an airplane are contributing factors to pilot fatigue. These effects are less extreme in modern civil aircraft than in military planes. It should be kept in mind, however, that the noise and vibration in the cockpit are much greater than those in the passenger compartments of most civil aircraft.<sup>41</sup> Unfortunately, there are few controlled studies dealing with the effects of noise and vibration in aircraft on pilot performance and fatigue. Many pilots believe that these are significant factors, especially in flights of extended duration. A number of fatiguing influences that should be carefully controlled are as follows: the pilots' seats should be free of vibration and located conveniently near the controls and instruments; the navigating tables should be cushioned, to prevent excessive vibration; the cockpit should be well illuminated at night; radium paints should be eliminated on the dials because of the possibility of noxious effects from the radium; metal surfaces, which give rise to glare, should be eliminated; attempts should be made to reduce the static in the earphones; and the ventilation and temperature should be well controlled, to avoid extremes. All these variables may contribute to pilot fatigue individually or collectively. The flight surgeon should study every factor that affects the health or efficiency of the pilot. Most of these adverse conditions can be corrected by aeronautical engineers.

#### *Experimental Studies in Trans-Pacific Flights*

A study of fatigue in transoceanic airmen was carried out on a routine flight of the Pan American clipper between Alameda, California, and Manila, Philippine Islands, and return, to analyze the fatiguing effects of prolonged flights at altitudes averaging 9460 feet on 17 airmen and 11 passengers. The total flying distance of 14,141 nautical miles involved one hundred and twenty-two and one-half hours in the air. A series of physiologic, biochemical and psychologic studies were made at the various island stations. The following conclusions may be drawn from the data obtained on these airmen and passengers:

The subjects, both airmen and passengers, maintained a high degree of neurocirculatory efficiency throughout the flight, as judged by the individual items and composite score of the Schneider index. When the test was given in the basal state,—that is, before ascent,—none of the airmen tested below +7, a score frequently related to a significant degree of fatigue or unfitness in aviators. Of one hundred and forty-two tests in the basal state, only 2 subjects tested below +10, the average being +13, which is close to the mean of +14.8 for college athletes. The average basal state (fifty-four tests) was +11.5, only three tests falling below +7 throughout the flight. The mean score for the group at high altitude was +10.8. In a total of ninety-six tests given at a mean altitude of 9500 feet, only four fell below +7.

There appeared to be a general tendency toward low blood pressure as the flight progressed that was similar to the blood pressure observed in acclimatized workmen at high altitudes in the Andes. Six of the 8 airmen (the mean age for the group was thirty-two years) had systolic blood pressures below 110. The initial response to altitude usually showed an increase in pulse rate and an increase in systolic blood pressure, followed by a well-controlled fall to normal values if the subject remained at rest.

As the flight progressed, the pulse rate tended to show a greater increase after exercise and to take longer to return to normal. As might be anticipated, this was also true at high altitudes.

There was a consistent decrease in the Schneider indexes in Manila. This was related to the increased pulse rate caused by the high humidity and temperature of that region. After the subjects rested two days in Manila and slept in air-conditioned quarters, there was an improvement in the Schneider indexes. After a rest period of one week in Honolulu, there was a slight decrease in the mean Schneider index for the 8 airmen.

There was a tendency toward polyuria in these airmen, as commonly observed in athletes previous to competition, particularly in those who shared the greatest responsibility in handling the ship. As the flight progressed and the airmen became acclimatized, the polyuria diminished.

The partial pressure of oxygen and carbon dioxide in the alveolar air and arterial blood of these airmen was similar to values considered normal for acclimatized men at similar altitudes,

of the sensations of fatigue. In athletics, such as in crew or track, the transport of oxygen from the blood to the muscles is impaired, and it is for this reason that even small amounts of alcohol are detrimental and cut down performance by the fraction of a second necessary to win a race.

Recent research on the effects of alcohol has revealed a number of interesting facts for pilots and air passengers. Possibly one of the most direct effects of alcohol on the organism is that of diminishing the utilization of oxygen in the tissues. There is a close similarity between the behavior of a person suffering from acute oxygen deprivation on a mountain, in an airplane or in a low oxygen chamber at sea level and that of a subject under the influence of alcohol. The effect on the nervous system under both conditions is essentially the same—that is, a deficiency of oxygen is delivered to the tissue. At high altitude, there is a deficiency of oxygen in the inspired air, and under alcoholism there is a hindrance in the transport of oxygen from the blood to the tissues.

The frequent references to the similarities in behavior between the effects of alcohol and of oxygen want (anoxia) and the fact that acute alcoholism could be counteracted by breathing excess carbon dioxide led McFarland and Barach<sup>31</sup> to analyze the concentration of alcohol and lactic acid in the blood following the ingestion of standard amounts of alcohol in an oxygen chamber filled with air and at other times with excess oxygen (50 per cent) and excess carbon dioxide (2 to 5 per cent). The experiments showed that on the average both the blood alcohol and lactic acid were diminished during the breathing of excess oxygen and carbon dioxide as compared to the breathing of air. On the other hand, the alcohol was oxidized more slowly and the subjective effects accentuated when air deficient in oxygen was breathed. The experiments were repeated at 17,500 feet and 12,200 feet in the Andes, with similar results.<sup>32</sup> The significance of these findings for airmen is obvious. The effects of alcohol are greatly accentuated at high altitudes, and efficiency following the ingestion of alcohol is therefore impaired proportionally. The passenger who boards an airplane after drinking heavily may fall asleep quickly and forget his fears and worries. If the air is rough, however, he usually awakes and is more subject to airsickness. The pilot at that time, on the contrary, must be alert and efficient, and nothing should be involved to impair his nervous functions during the flight.

#### *Effects of Tobacco*

There are very few carefully controlled studies of the effects of smoking, and even less informa-

tion dealing with the effects of tobacco at high altitude. Modern advertising has tended to distort the facts regarding the effects of tobacco. The evidence from reputable university laboratories does not uphold the contentions frequently made that one brand of cigarette causes less acidity than another, or that any "lift" is due to an increase in blood sugar. It is obviously absurd that smoking necessarily goes with being a good athlete, explorer or aviator, as many cigarette advertisements imply.

The stimulating effect of tobacco is due to the nicotine, which is an alkaloid. Nicotine is poisonous, and in small quantities has an effect similar to other alkaloids (morphine, strychnine and cocaine). The commonly alleged soothing effects of smoking tobacco are due primarily to the nicotine. A number of carefully controlled studies indicate that smoking gives rise to the following reactions in the organism, largely through stimulation of the autonomic nervous ganglia: an increase in pulse rate, especially noticeable when one smokes before breakfast; an initial rise in systolic blood pressure, followed by a fall immediately after the smoking period, which may account for the dizziness often noticed by the inexperienced smokers; constriction of the blood vessels, particularly in the periphery of the body; a slight impairment in keenness of vision—since the eye is the most sensitive of the special senses, these effects are manifested in visual functions more readily than in hearing; inhibition of digestive movements of the stomach—it is from this effect that the smoker may temporarily allay his hunger; effects on the surfaces of the lungs, which give rise to breathlessness on exertion. There is some evidence that the carbon monoxide from smoking affects pilots adversely; although the amounts are small they are believed by many to be damaging at high altitudes and relatively innocuous at sea level.

During World War I, a series of studies was carried out on aviators relative to the effects of smoking.<sup>33</sup> The results indicated that in 75 per cent a single cigar or the inhalation of one or two cigarettes had definite though temporary effects on vision and caused an increase in pulse rate and a rise in blood pressure. The visual effects were manifested in terms of reduced visual acuity and ocular muscle balance. Only a few nonsmokers were studied. In these cases, some giddiness occurred at eighteen to twenty minutes from the start, and was accompanied by slight nausea.

It is therefore obvious that excessive smoking has a detrimental effect on the pilot's acclimatization to high altitude. It tends progressively to

## THE TREATMENT OF WAR WOUNDS OF THE BRAIN\*

GILBERT HORRAX, M D †

BOSTON

IT is quite obvious that a discussion of the treatment of war wounds is most pertinent at the present time. This paper is designed to cover not only actual gunshot wounds of the brain but also similar injuries due to fragments from shells and from bursting bombs, the latter being probably even more frequent in this war than the ordinary types of wounds from penetrating missiles.

### PROPHYLAXIS

Since this subject is so obviously a war topic, a few remarks concerning what may be done by way of prophylaxis to lessen the severity of head injuries appear to be in order. In the first place, it would be most desirable if all soldiers could go into action with closely cropped hair. This would not only minimize the amount of hair that would be driven into the brain in penetrating injuries but would also prevent a great deal of infection of the lacerated scalp wound from the long hair, which becomes matted with blood and frequently incorporates itself within and contaminates the laceration. Furthermore, the shaving and sterilization of the area around any such wounds would be infinitely easier.

Secondly, tetanus toxoid has been shown to be a most valuable prophylactic agent and should be given to all soldiers and civilians likely to be involved in enemy actions. The usual dosage consists in 1 cc subcutaneously as a first injection and a second injection of the same amount two or three months later, a third injection after another two or three months is advisable. If it is known that this series of immunizing injections has been complete, 10 cc of tetanus toxoid should be injected subcutaneously at the time of injury; in the absence of complete immunization, 1500 units of tetanus antitoxin should be given immediately in all cases with compound injuries.

\*Presented at the annual meeting of the Massachusetts Medical Society Boston May 22, 1941.  
†From the Department of Neurosurgery, Lahey Clinic.  
†Neurosurgical, Lahey Clinic.

Thirdly, the sulfonamides should be given by mouth at the earliest possible opportunity after a compound injury of any kind has been received. An initial dose of 6 gm of sulfanilamide should be given by mouth if it is possible for the patient to swallow, if the patient cannot swallow, it should be given through a nasal tube. Subsequent doses at four hour intervals, so that patients receive approximately 6 gm daily, should likewise be administered.

### GENERAL PRINCIPLES

It must be remembered that all penetrating brain wounds due to shell fragments, bullets, bomb fragments and so forth are compound fractures. One of the greatest essentials is to get these patients to a hospital or post where complete treatment can be carried out for their wounds at the earliest possible moment. So far as immediate or delayed surgical shock will permit, it is highly desirable that operative treatment, when it is indicated, be undertaken within twelve hours of the time of the infliction of the wound, and earlier if possible, since the sooner these wounds can be debrided the less the chance of subsequent infection and thus of complications, which so often either are fatal or produce untoward late effects ‡.

It must also be remembered that many patients, especially those who have multiple wounds elsewhere on the body or extremities, may first of all need treatment for serious shock. This must be combated in all possible ways by warmth, hot drinks, infusions of serum or plasma or transfusions of blood, the guarded use of small doses of morphine, and quiet and complete rest so far as this is obtainable. Infusions and transfusions can be carried out while the patient is being operated on; they should not be delayed too long before operation is undertaken. In addition to the care de-

‡It is possible that with the present more perfect methods of wound debridement together with the use of sulfonamide operation with primary closure may be delayed from twelve to twenty-four hours if necessary.

ing, has penetrated the underlying brain to varying distances, sometimes going in as far as one of the cerebral ventricles (Fig. 1); simple penetrating wounds, which are usually due to a rather large, single metal fragment that has carried in with it fragments of bone and other debris and has lodged somewhere within the brain, not infrequently penetrating the ventricle and sometimes crossing to the opposite side of the brain from that on which it entered (Fig. 2); pene-

tions, such as cerebrospinal-fluid leak or intracranial aerocele, may develop.

*The gutter type of wound and wounds due to a large, single penetrating fragment.* The operative treatment of wounds of the first two types may be considered together, since they are essentially similar in most of their aspects and in general require the same type of treatment.

After careful excision of the contaminated portion of the scalp, radiating incisions should be

FIGURE 3. *Excision of the Bony-Penetration and Depressed-Skull Area by Bone-Cutting Forceps after Exposure of the Area by Reflection of the Scalp. (Modified from Cushing.<sup>2</sup>)*

trating wounds from multiple and often small fragments, particularly bomb splinters—this type of injury has been particularly prevalent in World War II; through-and-through or perforating injuries, which usually have a small wound of entrance and a much larger wound of exit, with a certain number of bone fragments carried in along the track; wounds involving one or another of the air sinuses, more particularly the frontal and ethmoid sinuses, in which subsequent complica-

made from the area of scalp laceration, usually in the form of a tripod, so that the flaps thus created may be retracted and an adequate exposure of the fractured area secured. The break in the skull is a relatively small round opening or a rather large, irregular hole in wounds due to a large metal fragment, and the bony defect is a long elliptical area in gutter wounds. Four burr openings are made surrounding this bony defect and including the depressed fracture area,

and these openings are connected with bone cutting forceps, a procedure that enables one to lift out the whole bony area intact and thus to expose the dura with either a small or a large perforation (Fig. 3). At this point, the procedure of choice varies according to whether or not an electrosurgical apparatus, together with adequate suction, is available.

If these two adjuncts are not at hand, a method similar to that employed during the first war, as advocated by Dr. Harvey Cushing, is in order. If the patient is under a local anesthetic, he is asked to strain or cough, and by this means considerable amounts of clots of semisolid contused brain may be expressed through the hole

being withdrawn from time to time and such material as has been sucked up into it is then discharged out of the field of operation (Fig. 4). In this way, all bone fragments and other debris may eventually be completely removed from the contaminated area in the brain. It is essential to remove every indriven bone fragment in this manner, and it is likewise advisable to remove the metal foreign body, which as a rule is found down at the bottom of the track, if this can be done without undue difficulty and without further damage to the brain. The metallic fragment can sometimes be located with the catheter, and a delicate, alligator forceps can then be inserted

FIGURE 4 Catheter and Syringe Method of Debridement of the Track in the Brain (Cushing\*)

*The softened, disorganized tissue is sucked out, the bone fragments and other foreign bodies are palpated with the catheter and removed by delicate forceps*

in the dura, and such material may then be wiped gently away from the remainder of the wound. Indeed, small bone fragments may sometimes be thus extruded. A soft rubber catheter of suitable size is then inserted gently through the hole in the dura, and with this catheter as a means of palpation, bony fragments along the track of the missile are gently searched for and removed either by gentle suction with a syringe attached to the end of the catheter or by a grasping of the fragments with a delicate forceps and their extraction in this way. Gradually, as the catheter is inserted farther and farther in the track, the area is cleaned out by careful, not too vigorous suction on the catheter, thus, devitalized brain tissue, clots and other debris are drawn up into the catheter itself, the catheter

and the foreign body picked up and thus extracted. When the metallic fragment is of magnetizable material, it is often useful to insert a long, rounded nail down into the track in the brain so that it touches or nearly touches the metallic fragment. When this has been done, a powerful electromagnet is brought up to the end of the nail, and often the withdrawal of the magnet and the nail also withdraws the foreign body (Fig. 5). It is a long tedious process to clean out thoroughly a deep penetrating wound by the means thus described, and when this method is used, it is of the utmost importance not to disturb the dural edge and not to get out into normal brain outside the track created by the foreign body and bone fragments. At the end of such an operation, it is probably advisable to dust sulfanilamide or

sulfathiazole powder into the cleaned-out brain area; if the débridement is thought to be complete, if the operation has taken place within twelve hours of the injury, and if the patient can be followed for ten days or two weeks by the operator, primary closure should be made.

If an electrosurgical apparatus, together with strong suction, is at hand, a somewhat different procedure is preferable to the time-consuming and sometimes inadequate débridement possible by the catheter-suction method. Although it has

FIGURE 5. *Blunt-Nail and Electromagnet Method for Extraction of Magnetizable Metal Bodies.* (Horrax<sup>3</sup>; reproduced by permission of the publisher.)

not as yet been tried in combat or other war areas, I believe that the following procedure would be particularly applicable in wounds outside the motor and speech areas.\*

After exposure of the dura by the means already described, the membrane should be incised to a distance of perhaps a centimeter in a circular fashion outside the area of dural penetration, and then the whole track in the brain should be excised, together with its contained elements, in exactly the same way as a similar wound anywhere else would be excised. With the electrosurgical apparatus, an area slightly outside the actual track of the missile or bone fragments should be sealed off, that is, the blood

vessels on the surface should be sealed off around this area, and the brain incised in this coagulated area outside the track. Then, by a combination of strong suction, using a metal sucker, and with the electrosurgical coagulating current constantly applied to this sucker, one can clean out the soft brain surrounding the track, together with the clots and other debris (Fig. 6). If larger bone fragments are encountered, they can doubtless be taken out by the strong suction itself, or if they are too large for this, they can be extracted with delicate forceps. In this way, a core of tissue including a small amount of uncontaminated brain outside the track is completely removed by the combination of suction and electrocoagulation, the latter being employed to sterilize the area at the outside of the track as one proceeds. As the core of tissue is gradually removed, one can insert a flat spatula along either side of the cavity created, and thus débride the whole area under direct vision (Fig. 7). I am convinced that a much more complete and thorough débridement of all possible elements contained in the track can be accomplished in this way than by the older method. Any possible bleeding set up as this procedure progresses can be rapidly stopped by the electrocoagulation; finally, if a large foreign body requires removal from the bottom of the track, it can be seen and picked out very readily. When ventricular penetration occurs, the ventricle can be inspected and any debris removed from it. Again, as in the older method of treatment, wounds that have been completely débrided by the method just described should be closed primarily when patients are operated on within twelve hours after injury, after the local application of sulfanilamide or sulfathiazole powder within the wound.

When patients are operated on after the twelve-hour period following an injury, sometimes after one, two or even three days, the wounds show varying degrees of infection, which has sometimes gone on to an extremely foul-smelling herniation or fungous formation of the brain, with bone fragments and other debris extruding through the brain track. These wounds must be opened widely, and additional bone must usually be taken off around the area of penetration so that the dura can be incised in radiating fashion, thus relieving the almost certain constriction that exists at this point and is bottling up the infection inside. All devitalized tissue, bone fragments and other debris should be completely sucked away down into the track, which should be treated by open drainage of one form or another just like a brain abscess. It is my opinion that probably the best form of drainage in a case of this kind

\*I am informed by a neurosurgeon recently returned from England that this proposed method has been used there with excellent results.

is to insert gutta-percha tissue down to the bottom of the track, which is then packed widely open over this tissue with gauze. In any event, the track should be held widely open by some means, and in these cases it is probably best not to dress the wound for two or three days but to leave the original dressing, with its inserted

down to the diploe, from which granulations spring up and cover the bare bone much more quickly than if the granulating process were allowed to proceed merely from the edges.

*Multiple wounds made by small fragments.* It has been shown by British neurosurgeons during the present conflict that a very common type of

FIGURE 6. Procedure for Complete Excision of the Contaminated Track of Brain by Electrosurgery and the Suction Apparatus. (HORRAX; reproduced by permission of the publisher.)

*Incision of the dura (a) is made outside the track (dotted line), with subsequent removal of the whole area within the dotted line (c), after incision of the cortex just outside the penetrated area (b).*

drainage, in place so that a drainage track becomes firmly established. After that, the dressings can be changed either daily or every other day for the sake of cleanliness around the outside of the wound; as healing gradually takes place and infection subsides, the drain gradually extrudes and can be cut off a little each day. Finally, the area granulates, and if the exposure is wide, healing can be hastened by secondary suture or by some form of pinch grafts. If a wide area of bone has been exposed, it is sometimes an excellent plan to make perforations over this exposed area

head injury under existing conditions is the spraying of multiple small splinters of bomb casing into various parts of the body, including the head. These splinters are usually quite small, and because of their high velocity are almost red hot when they enter the body. Thus, they are sterile, and such material as may be carried in with them is probably rendered sterile. It has been found that much the best policy with these small fragments is to let them alone rather than to try to extract them operatively. Naturally, the scalp wound should be inspected and may need some

simple form of attention, either simple débridement and closure or perhaps only a simple dressing.

*Through-and-through wounds.* These wounds are usually made by machine-gun or rifle bullets that have passed from one side of the skull to the other through the brain; they are nearly always immediately fatal, but occasionally the patient survives and enters the hospital in fair condition. Very little need be done to these wounds as a rule. The wound of entrance is small and

FIGURE 7. Detail of the Procedure Depicted in Figure 6. (Horrax<sup>1</sup>; reproduced by permission of the publisher.)

The brain edges are retracted, and the track cleaned out by suction under direct vision.

should be débrided in the usual way to a limited extent, unless x-ray study displays indriven bone fragments that are fairly easily accessible. The wound of exit, which is much larger than the wound of entrance, should be débrided locally, and any loose bone fragments present should be picked out. As in other contaminated wounds, the local use of sulfanilamide or sulfathiazole powder is indicated. If the injury is seen in the early stages, and if the patient is to be kept under observation by the operator, the wound may be closed after débridement, to effect primary union.

*Wounds involving the air sinuses.* These are extremely serious wounds because, in addition to the compound fracture involving the brain, there

is the open sinus, which cannot be closed and which affords a site of continuing infection for a long period. In wounds that have traversed the frontal sinus, the usual débridement of the brain should be performed, as in other types of penetrating wounds. Any general fragmentation of the sinus should be cleaned away as well as possible, such portion of the mucous membrane as has been obviously contaminated or is dirty being removed. If the wound is operated on within the first twelve hours from the time of injury, the dura should be closed, if possible, and the area should then be packed widely open, with gutta-percha tissue or rubber dam against the dura, and with gauze over this for packing. Another method is to close the scalp wound, leaving a drain down through the frontal sinus and coming out of the nose. If such a wound heals by primary union, much time is saved for the patient, but this procedure is far less safe than the open method.

The particular danger present with wounds involving the brain and air sinuses is a cerebrospinal-fluid leak. To prevent this complication, it is imperative, when possible, to close the dura after careful débridement of the brain. If such closure is not possible, a muscle implant may be used over the ethmoid cells when this area has been opened, or a vaseline gauze pack may be placed against the dura and uncovered brain when the wound has involved the frontal sinus. If the wound has been closed either by primary union or by packing off, and if a cerebrospinal-fluid leak develops, the patient must be reoperated on, and the fistulous tract from which the leak is coming sought. This is most frequently just above the cribriform plate of the ethmoid, and this area should then be sealed off with a muscle graft.

Another occasional complication of wounds through the frontal or ethmoid sinuses is the development of an intracranial aerocele. This is caused by the introduction of air through some portion of the dural laceration, and the patient as a rule begins to notice some increasing headache after a sneezing or coughing spell. X-ray study reveals the collection of air in one or the other frontal lobe. This air usually means a fistulous tract between a frontal sinus or the ethmoid cells and the brain. It must be sought and covered with a muscle graft to keep the aerocele from connecting with the ventricle and thus to prevent the development of a cerebrospinal-fluid leak. In all these cases, the continued use of sulfanilamide by mouth is advisable, to offset any possible infection.

## POSTOPERATIVE COMPLICATIONS

Patients who have had serious gunshot or shell wounds of the brain and have been operated on should have their wounds looked at carefully every day for a period of ten days to two weeks or longer if possible. If obvious infection is developing as shown by puffiness and reddening over the operated area, the wound should, of course, be reopened promptly and left widely open, gutta percha or some other rubberized type of tissue against the raw brain area being used. It may be wise in some cases to suck out further devitalized material from the superficial portions, at least of the track within the brain, and to treat the track just as one would a brain abscess, that is, by open drainage and by some smooth form of tissue next to the raw brain surface. It is a serious matter when these wounds do not heal by primary union and have to be opened up secondarily in this way but it is not by any means a hopeless matter, since many of them heal in time with careful treatment, frequently, even a herniation or fungus eventually granulates and recedes and the wound covers over with epithelium in the usual way. When a fungus develops from this source, or when the patient has been operated on late and it is necessary to leave the wound widely open from the start, the fungus should be covered with some smooth material, such as gutta percha, as stated before, and then surrounded by a doughnut of cotton over which the usual gauze dressing is placed. The doughnut is used to prevent pressure on the fungus which can only do harm, since it is not possible to keep the fungus from protruding and indeed it is not advisable to try to do so since such protrusion represents an effort of the brain to get rid of pressure. To prevent too great herniation of brain in this way, it may be advisable to do daily lumbar punctures to reduce the pressure to a certain degree.

Other acute postoperative complications include meningitis and diffuse encephalitis. These can be treated only by keeping the pressure down, so far as possible by frequent lumbar punctures and by the general use of the sulfonamides according to the type of organism involved.

Another immediate postoperative sequela, especially in patients who continue to be either drowsy or stuporous for a long time, is the collection of mucus in the air passages. This must be repeatedly cleaned out by suction because if there is not a free airway and if mucus gets down into the bronchial tree, there is every likelihood of an atelectasis or another pulmonary complication. It is imperative to have some form of suction apparatus immediately available on all wards where unconscious or semiconscious patients are situated, because the collection of mucus is a serious matter that must be attended to promptly and frequently.

With the late complications of head injury, such as brain abscess, post traumatic convulsions, headaches, dizziness and neuroses, this discussion does not presume to deal.

## SUMMARY

In the treatment of gunshot wounds of the brain, stress should be laid on such prophylactic measures as can be instituted, particularly the use of tetanus toxoid and of the sulfonamide drugs. The second important feature is the urgent necessity of getting patients quickly to a hospital where complete operative treatment can be carried out for wounds that require such treatment. In general, the earlier these wounds can be treated, the better will be the chance of preventing subsequent infection. Certainly, whenever possible, patients should have their complete operation within twelve hours from the time of injury. No avoidable delay for other purposes can offset the advantages of early operation. Finally, a careful, complete and painstaking débridement of the wound, both of the skull and of the brain, should be carried out, preferably by those who are well trained in this type of surgery.

## WAR NEUROSES\*

DOUGLAS A. THOM, M.D.†

BOSTON

WAR neurosis is a three-dimensional problem. Its length can be measured only by time, which reaches from war to war. The casualties of World War I remain a tremendous medical problem, and the effect of the present European conflict is already bringing out evidences of nervous instability in the civilian population. Modern warfare includes men, women and children of all ages. Its breadth encompasses all the neurotic and psychopathic disabilities of civil life and includes practically every symptom in the whole category of medicine. Its height can be appreciated if one studies the report of the Administrator of Veterans' Affairs for 1940,<sup>1</sup> which reveals that 58 per cent of all patients being cared for in veterans' hospitals have neuropsychiatric disabilities. The economic aspect of the problem is appalling when one considers the money spent on training, compensation, pensions, hospitalization and treatment.

The war neuroses begin early. They are long drawn out and difficult to treat, and tend to increase for at least twenty-five years after the cessation of hostilities.

There are three definite points of attack on the war neuroses. First, in the selection of the men who are to enter military service, secondly, in helping to maintain the morale and caring for the mental casualties during combat service and, thirdly, in aiding the soldier during the period of demobilization toward rehabilitation and readjustment to civil life. The problem might well be considered in the light of these three outstanding phases of the soldiers' military experiences: mobilization, combat service and demobilization.

## MOBILIZATION

The local draft boards operated in much the same manner in 1917-18 as selective-service boards do today, weeding out the obvious misfits as they came along and depending more and more on the induction boards to make the final decision of fitness for service as time went on. The monotony of the routine examinations became apparent, and medical standards, which were set very high during the early part of the draft, were sustained with difficulty. The induc-

tion boards were called on to scrutinize the prospective soldiers more carefully, to eliminate the undesirable ones.

Approximately 3,500,000 men were examined by the neuropsychiatrists at the mobilization centers, and 69,394 were rejected because of some mental aberration. Approximately one third were mentally defective, one sixth were psychoneurotic, one tenth were psychotic, and about the same number were epileptic. The remaining one fourth were inebriates, drug addicts and victims of other neuropsychiatric instabilities. As the war continued and more men became engaged in combat service, the mental casualties increased to a rather alarming extent, and finally a request came from abroad that a more careful selection of men be made on this side before sending them overseas for active service.‡

The physical stresses and mental strains of camp life served as a test for the mental stamina of the soldier, and a screening-out process eliminated many from service overseas. The intimate social contacts of camp life, the arduous military training and the exacting disciplinary measures constituted an experience that was too taxing for certain prospective soldiers to meet adequately. The adaptations that had been built up to civil life began to break down. The men whose intellectual endowments were definitely limited were looked on by their comrades as being stupid, and by their officers as being indifferent. The soldiers were right. But it was the duty of the officers to train these men; hence they were rebuked, humiliated, assigned to kitchen police and other unpleasant tasks and punished; finally, in revolt, they became defiant, went "AWOL," and landed in the guardhouse. Usually, the offenders were seen and examined by the psychiatrist and eventually rejected as being unfit for military service.

It is of interest to note in passing that the psychologic examinations given to groups of perhaps a hundred or more men at one time indicated that intellectually it was the men who fell in the low 10 per cent that made up a large number of the chronic offenders, and it was the high 10 per cent from which many of the noncommissioned officers were recruited. These tests were found to

\*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 22, 1941.

‡The following extract is from a cablegram sent by General Pershing on July 15, 1918: "Prevalence of mental disorders in replacement troops recently received suggests urgent importance of intensive efforts in eliminating mentally unfit from organizations of new draft prior to departure from the United States."

give a very adequate measure of the relative intellectual equipment as well as the practical ability of the soldiers, and there was a fairly close correlation between their test scores and their achievements.

There were the shy, sensitive, timorous lads who found the bayonet drills and the practice of running the dummies through under the direction of the enthusiastic masters of military technique a bit too realistic, and who became the victims of their own vivid imaginations and undue sensitivity. Some developed physical symptoms such as nausea, vomiting, fainting, tremors and insomnia, others developed the more serious mental symptoms that are so common in the anxiety states. Some men became morbid and depressed with definite psychotic symptoms. Every type of mental disorder was precipitated by the inability of the predisposed to meet the demands of camp life. These experiences did not cause the disease, they simply brought in existing instability to the surface where it could be recognized.

Such were the cases that were returned from the camps to civil life or held for noncombatant service. A recognition of these potential neurotics prevented them from developing a more serious mental disability overseas, where the problem of care and treatment would have been tremendously increased.

It is difficult to reconcile the rather superficial neuropsychiatric examinations that are being made at the present time, — limited to about seven minutes for each man, — with the gravity of these casualties both from a military and from an economic point of view. It was recently stated that adequate psychiatric examinations which would weed out the potential neuropsychiatric disabilities would save the Government \$500,000,000 for every million draftees.<sup>3</sup> It has been estimated that every psychotic soldier who breaks down in the Army costs the Government \$30,000 from the time of the onset of his disease until his death.<sup>4</sup> If psychiatrists can be hired at the rate of \$15 a day it takes but a little mathematical reckoning to determine that if one psychiatrist picked out one potential psychotic every six years, he would save the Government his salary.

#### COMBAT SERVICE

The neuropsychiatric disabilities resulting from active military service represent the war neuroses of the American forces of the first war and the shell shock of the British. They are made up of so many and so varied heterogeneous groups that it would be a time-consuming task of but little value to define the limitations of each. In the order of their frequency, and including a very

large percentage of all the neuropsychiatric disabilities, they are neurasthenia, conversion hysteria, anxiety states and the psychoses.

The underlying mechanism of the disability is pertinent to this discussion. The war neuroses represent a group of neuropsychiatric disabilities incurred in military service and resulting, on the one hand, from conflict between acquired social attitudes — such as loyalty, patriotism, honor and the maintenance of one's personal customs and traditions, as well as those of the army, regiment and company, all of which Trotter includes under the term 'herd instinct' — and, on the other, from the instinct of self preservation. These sets of dynamic forces, although always present are under ordinary conditions not in serious conflict, inasmuch as the 'herd instinct, or the so called 'social drive,' is allowed to operate more or less freely, unhindered by any interference from the instinct of self preservation. Only under conditions such as war, floods, earthquakes and panics, in which there is a direct threat to one's existence, does the instinct of self preservation assert itself and become a dominating force.

The purpose served by the neurosis, as stated, is that of protection, and to be adequate and fulfill the purpose for which it is psychologically designed, the neurosis must protect both the soldier's ego and his physical being — that is, it must permit him to escape from the intolerable situation created by the impending dangers of war on the one hand and to accomplish this without loss of self respect on the other.

Since neurosis has been recognized as a medical problem, with symptoms comparable to those of any other illness and since neurosis has been accepted as a medical entity by those in authority, both medical and military, and by the soldier, the public and the press, it has not been difficult for the soldier to accept his disability as a way out of a difficult situation. Consequently, a neurosis solves the conflict between the herd instinct, which drives the soldier on to perform his military duty and to live up to those socially acquired traditions and his personal ideals of what he would like to be and the instinct of self preservation which is constantly threatened by the dangers of pursuing the paths of duty.

It is of interest that neurosis was rarely observed in men at the front or in those who had been wounded and were in base hospitals. However, a certain number of wounded men developed states of anxiety as the time approached for their discharge from the hospital especially if they were assigned to active military duty.

Neurasthenia, the anxiety states and the psychoses had a fairly equal distribution among all

those engaged in military service—officers and soldiers alike. The so-called “conversion hysterias,” however, were found in an overwhelming degree in the more suggestible, less well intellectually endowed soldiers, and were infrequently seen in the officers. These physical manifestations of mental conflict, such as the paralyzed arm or leg, functional blindness, deafness, aphonia, and the more violent tremors and muscular twitchings, represented what might be termed a rather crude method of solving the conflict. In other words, the average soldier confronted with danger met the situation promptly, decisively, and without any great struggle to carry on, whereas the neurasthenic did not. He developed a syndrome with such symptoms as fatigue, insomnia, battle dreams, anxiety and depression, frequently lasting over a period of weeks or months before completely incapacitating him. Many of these men went in and out of the front-line trenches month in and month out until they finally reached the breaking point.

Treatment of the conversion hysterias was usually not difficult. The patients responded readily to methods of suggestion, such as the faradic battery, isolation and hypnosis. However, it was found from experience that as a group they had little to contribute to military service. The other types of cases—the neurasthenias, anxiety states and the compulsive and obsessional neuroses—invariably required long periods of rest and prolonged psychotherapy. It was the experience of the medical officers in the American Expeditionary Force that severe cases of war neuroses that required evacuation to base hospitals were rarely good risks for further front-line service. The origin and purpose of the neurosis is to protect the patient from a situation which he is inadequately prepared to meet because of a poorly organized nervous system and a poorly integrated personality make-up. To return these men to the same situation that created the initial breakdown was a hazardous undertaking. The experiences of the American Expeditionary Force and those of the British Expeditionary Force during the first war were not particularly different from the experiences of the British at the present time.

Debenham, Sargent, Hill and Slater,<sup>6</sup> in a recent article dealing with 1550 cases of neuroses or psychoses in members of the armed forces, state:

In the early months of the war, cases were largely those men who should never have been regarded as fit for military service. . . . At evacuation of Dunkirk another type predominated, acute anxiety or exhaustion syndromes in men of apparently normal personality,

who had not broken down until placed under considerable strain. . . . It is useless to send a man back into army life merely because he is symptom free if he is liable to break down under small strain. An assessment must be made of the personality and of the strains that it is able to support. The longer the neurotic reaction is allowed to persist, the more difficult it is to deal with.

In contrast with American and British attitudes toward the war neuroses, I quote from a book by Martin Gumpert,<sup>7</sup> which presents the German medical and military point of view:

War hysteria and “trembling” are mere cowardice, masquerading as sickness. It is wrong to cater to war-hysterical people. How then shall the army administration treat them in the future? First, and at once, *they must be brought to a war hospital. Their stay in the war hospital will be short and the hospital not too close to home. They must realize that they are to face conditions which will not at all accord with their wishes. Unfortunately, it is not possible, for obvious reasons, to send back to the front men who cannot be cured of their nervousness in the war hospital. Normal men would not understand the reasons why such “poor sick people” should be left in the trenches; morale would suffer. Obstinate cases must be united in special squads and sent to places where they can be put at physical work, without consideration for their nervousness. This work must not be too far from the front, but must be right up in the danger zone—road building, trench work, etc., where the risk is no less great than for the soldiers in the front lines. These men must be forced, without consideration for their neurosis, to those kinds of work which normal individuals might do, because such “trembling” cannot be counted as a sickness. Therefore, war-hysteria, even should it increase, will not be reason enough to remove anyone from the war zone; indeed the strongest pressure must be used upon him to make him fulfill the tasks assigned to him.*

It is obvious from American and British experience that the war neuroses as they develop in line of duty represent an extremely difficult type of medical casualty and that therapy should be applied at the earliest possible date not too far removed from the scene of conflict. A fairly large percentage of patients can thus be rehabilitated in a relatively short time and sent back to active service. The cases that do not respond to this type of therapy and require evacuation to base hospitals can usually be rendered symptom free, but it is probably not wise, from a medical point of view, to return the patients to combat service. Many of these men were able to carry on in the Section of Supplies, and rendered a valuable service. However, thousands during the last war (approximately 3000 psychotic and 5000 psychoneurotic soldiers) had to be evacuated to the United States.

## DEMILITARIZATION

It is my opinion that more men suffered from artificially created neurotic conditions during the period of demobilization than from neuroses that developed on the battlefields of France. Literally thousands of men passively succumbed to a life of dependency on the Government and eventually became incapacitated for a self respecting, independent existence, owing very largely to the oversolicitous service organizations and the unwise distribution of pensions brought about by national sentimentality and political pressure. During the period of demobilization, various national organizations, with the best of intentions, asked soldiers to make claims for disabilities that could by no stretch of the imagination be considered medically valid. It was not for incapacities already existent but in an anticipation of what might possibly occur that many of these claims were made. These men became the unwitting victims of demoralizing subsidies from a paternalistic government.

When men are paid for being sick and penalized for getting well, the medical profession has little or nothing to contribute. The danger of building up a large group of veterans showing pseudoneuroses or compensation neuroses was entirely ignored. There is perhaps no period in the whole experience of military service that is more critical for the future happiness and efficiency of the soldier than this period of demobilization. It is also important to the Government from an economic standpoint, as well as for the preservation of man power. Psychiatry could have contributed much during this period for the welfare of both men and the Government. There was no real need for hurry during demobilization. It might have been an opportunity for carrying out a well co-ordinated plan for reorienting a certain group of men to civilian life after their war experiences. As history shows, it was anything but that. It could not be done through compensation alone.

Another phase of demobilization that contributed to many maladjustments later on was the hurried, haphazard procedure of placing men in civilian training. Many men were encouraged to take up some form of training for which they were intellectually unfit. Being ambitious, many were lured into attempting to become doctors, lawyers, public accountants, artists and engineers, and into other professions for which their education before or during the war in no way prepared them. They gave up their prewar occupations and lost interest in the pursuits that they were equipped to follow. Failure resulted from the great gulf that existed between their ambitions and their abilities. It is hoped that such obvious mistakes will be eliminated during the next period of demobilization. It is one aspect of the whole situation from which the ex soldier should be safeguarded.

\* \* \*

In conclusion, I repeat that the war neuroses represent one of the most significant military and economic problems with which the Government has to deal. Every effort should be made to select men with care, to organize medical centers where adequate treatment can be administered during combat service, and to give careful consideration to the problem of rehabilitation after military activities have ceased.

## BLOOD AND BLOOD SUBSTITUTES IN THE TREATMENT OF HEMORRHAGE, SECONDARY SHOCK AND BURNS\*

STUART MUDD, M.D.,† AND EARL W. FLOSDORF, Ph.D.‡

PHILADELPHIA

SECONDARY shock may result from extensive operations, from the severe injuries of civil accidents or military wounds, or from burns, severe infections, profound anemias and other conditions.<sup>1</sup> Loss of blood, emotional stress, prolonged exposure to cold, and physical and nervous exhaustion may all be contributing factors. The cycle of deranged function that characterizes the shock state essentially involves injury to and loss of tone of the blood capillaries, loss of fluid and plasma proteins through the capillaries, and tissue anoxia (oxygen-deficiency). Unless this vicious circle can be broken, circulatory failure and death ensue. The mechanisms involved have been well summarized by Moon,<sup>2</sup> who has contributed extensively to their elucidation. The following is quoted from Moon<sup>3</sup>:

Endothelium is delicately sensitive to lack of oxygen, to metabolic products, cytoplasmic substance, bacterial toxins and to a wide variety of chemicals and drugs. When affected by any such substances, the endothelium becomes relaxed, atonic and abnormally permeable to blood plasma. The sequestration of blood in dilated capillaries reduces the effective blood volume, and the leakage of plasma into tissue spaces lowers the total blood volume. This creates a disparity between the volume of blood and the volume-capacity of the vascular stream bed. This disparity, if not compensated, causes circulatory deficiency.

Compensation is accomplished through responses activated probably by impulses from the carotid sinus. Activity of the sympathoadrenal system causes constriction of peripheral arteries, the discharge of reservoir blood from the spleen into the systemic circulation and stimulation of the heart by the adrenal medullary hormone. So long as the mechanism of compensation is effective there is no marked decline in the blood pressure, but the latter is maintained at the expense of volume flow which is reduced markedly. This stage of shock can be recognized by the presence of hemoconcentration. A progressive decline in the blood pressure signifies that compensation is failing and that the end is near. It is a sign of departed opportunity.

Capillary atony in extensive areas reduces both the total and the effective blood volume and leads to a reduction of the volume flow. This reduces the delivery of oxygen to the tissues. When the supply of oxygen falls below physiologic limits, it augments the capillary atony. Moderate lack of oxygen causes dilatation and hyperpermeability of capillary walls. This effect introduces a self-perpetuating quality which operates as a vicious circle and leads to irreversible changes.

Successful management of shock requires early recognition and effective measures for breaking the vicious circle. These will be directed toward removing the cause, toward increasing the blood volume and toward relieving anoxia. Saline solutions and artificial colloidal solutions are ineffective or objectionable. Transfusion of whole blood, except after serious hemorrhages, is not advisable. The ideal substance is that which has been lost from the circulation—plasma. Infusions of human plasma or serum should be given when hemoconcentration indicates impending circulatory failure and before the arterial blood pressure declines. Oxygen should be given by inhalation to counteract anoxia.

Although there are still points of controversy about the relative importance of the various mechanisms of injury that lead into this cycle of shock, there is general agreement that the critical factor whose correction is the most immediate necessity is the depletion of the volume of circulating fluid. The volume of the circulating fluid must be restored to normal as quickly, and maintained as nearly normal, as possible. For other measures in the treatment of shock, more general discussions should be consulted.<sup>4-7</sup>

For restoring the circulating-fluid volume, intravenous infusions of various fluids made isotonic by diffusible solutes, such as sodium chloride and glucose, have been tried. In general, such fluids offer only temporary relief because of the rapid loss of the added solute from the circulation into the extravascular fluids. Various fluids containing nondiffusible solutes, such as gum acacia, hemoglobin and bovine serum albumin, have been or are being tried. These fluids may have notable advantages from the standpoint of availability and low cost. In general, however, they result in the introduction of foreign substances into the circulation, and no one of them has yet passed successfully through the stage of clinical proof of efficacy and harmlessness. One of these artificial solutions may, of course, ultimately prove to have wide usefulness.

The ideal physiologic corrective for the depleted circulating-fluid volume of secondary shock in man is obviously human plasma or serum. Both plasma and serum have had wide trial in experimental shock (dog serum or plasma being employed in dogs),<sup>4, 8-10</sup> in postoperative clinical shock, and in that following civil accidents, burns or war wounds (human serum or plasma being used).<sup>6, 9, 11</sup> There is general agreement among workers in Great Britain, Canada and the United

\*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 22, 1941.

†Professor of bacteriology, University of Pennsylvania School of Medicine.

‡Assistant professor of bacteriology, University of Pennsylvania School of Medicine.

States that either plasma or serum, properly prepared and administered, is an optimal corrective for the depleted circulating-fluid volume of shock.\*

There has been a great deal of discussion about the relative merits of plasma and serum for the treatment of shock. It seems that for the purpose of restoring circulating volume there is little difference between them; intravenous infusion of either is efficacious. The advocates of plasma point out that it is possible, by immediate drying of the plasma from the frozen state, to preserve the prothrombin and complement as well as the globulins and albumin of the plasma, and that more plasma than serum can be prepared from a given volume of blood.<sup>11-13</sup> The advocates of serum point out that, since the essential value of the blood proteins in the treatment of shock lies in their colloidal osmotic pressure, the additional preservation of prothrombin and complement has little practical value under the circumstances in question, and that, moreover, serum is easier to prepare and requires somewhat less exacting conditions of administration.

A second point of controversy between the partisans of serum and those of plasma has been with regard to reactions on injection. The consensus seems to be that plasma, either fresh or regenerated after drying from the frozen state, may be given intravenously with no more fear of reaction than in the transfusion of whole blood. Serum that has been aged several weeks before administration or before drying for preservation may be administered with equally little risk of reaction. Some specimens of serum that have been preserved by drying shortly after taking off the clot have caused reactions, but these reactions seem to have been due to special conditions quite outside usual practice in preparing serum.

In current practice, serum and plasma for the treatment of shock are prepared in large pools representing many donors. Such pooled plasma or serum may be administered intravenously without regard to the blood type of the patient.

The question of whether serum or plasma should be concentrated, normal or diluted when administered in shock requires discussion. In general, this decision apparently depends on the condition of the patient; the aim should be to restore as nearly normal conditions as possible. If shock is complicated by concussion, as in accident or war cases, there may be a definite advantage in giving hypertonic, concentrated plasma or serum, which withdraws fluid by osmosis from the central nervous system and tends to restore the circula-

tion to normal.<sup>14, 15</sup> If the patient is markedly dehydrated, a condition that may occur after burns or military wounds, there may be advantage in giving dilute plasma or serum in large volumes. In other circumstances, isotonic plasma or serum may be indicated. Estimation of hemoconcentration or hemodilution by hematocrit readings, hemoglobin determinations or otherwise may afford useful indications of what is required. A rising hemoglobin percentage or an increase of the cells-to-plasma ratio indicates hemoconcentration due to loss of plasma through the capillary walls. When there has been extensive loss of blood, it may be well to follow the immediate treatment of shock by transfusions of whole blood.

It is of course simpler and more economical when practicable to keep plasma or serum in the liquid state. However, under conditions requiring prolonged storage or transportation, as for war purposes, and when concentration is desired, preservation by drying presents great advantages. Drying from the frozen state is generally conceded to be the method of choice, and is the method currently used in the preparation of dried plasma and serum for war purposes.<sup>5, 7</sup>

Several procedures and apparatus currently used for drying from the frozen state have been described under the terms "lyophile," "cryochem"<sup>16</sup> and "desivac."<sup>17</sup> In each of these processes, the plasma or serum is frozen and then desiccated in a vacuum at a rate sufficient to keep it frozen by the continued cooling incident to the loss of the latent heat of vaporization. The three procedures differ essentially in the means used to remove the water evaporated from the material undergoing desiccation. In the lyophile process, the water vapor is condensed as ice in a bath kept cold by dry-ice; in the cryochem process, the water vapor is absorbed by Drierite, a specially prepared, regenerable calcium sulfate desiccant; in the desivac procedure, the water vapor is trapped in the oil of the large vacuum pumps used, whence it is continuously separated by centrifugation. For drying small volumes, that is, up to about a liter daily, the cryochem apparatus has proved to be the most economical in operation, and for larger volumes, that is, from one to many liters daily, the desivac apparatus is the most efficient.

For use in the present war, large volumes of liquid and dried human serum have been and are being prepared in Great Britain. In the months before this undertaking was organized,<sup>18</sup> much liquid plasma was prepared in Greater New York, through the collaboration of the American Red Cross and the Blood Transfusion Betterment Association, and shipped to England. Large amounts

\*Concentrated solutions of human serum albumin, now under investigation by Drs. E. J. Cohn and Charles A. Janeway, may prove to have distinct advantages.

of liquid and dried serum are being prepared in Canada for war purposes. Large volumes of dried plasma are now being prepared in this country, with the collaboration of the American Red Cross, for the use of the United States Army and Navy.

For civil use on a small scale, plasma may be prepared directly from fresh whole blood, or plasma or serum may be prepared from blood stored in blood banks until the corpuscles must be discarded. Because of reactions Strumia et al.<sup>11, 12</sup> warn particularly against the administration of fresh (twenty-four to forty-eight hours' old) serum or serum vacuum-dried when fresh; such reactions have rarely been encountered with plasma or with serum held for several weeks in the liquid state before administration or drying. Human plasma and serum prepared by several of the large manufacturers of biologicals have recently been put on the market, but their price is high, owing to the cost of collecting and preparing such products.

#### SUMMARY AND CONCLUSIONS

The role of blood and blood substitutes in the treatment of hemorrhage, secondary shock and burns is briefly discussed.

Human plasma and serum are the most effective agents for restoring the volume of circulating fluid to normal in cases of shock and burns, as well as of hemorrhage in the absence of excessive bleeding.

Although serum and plasma are most easily and economically preserved in the liquid form,

drying from the frozen state by the lyophile, cryochem and desivac processes is recommended for war purposes and under conditions requiring prolonged storage or transportation.

## MEDICAL PROGRESS

ISOIMMUNIZATION IN RELATION TO INTRAGROUP  
HEMOLYTIC TRANSFUSION REACTIONS\*

SINFORO B. HOOKER, M.D.†

BOSTON

POST-TRANSFUSION reactions of the hemolytic type are most commonly ascribable to intergroup incompatibilities. These accidents have occurred because of mistakes in grouping the blood of the donor or the recipient, and occasionally<sup>1,2</sup> have been due to the use of a Group O (so-called "universal") donor whose natural isohemagglutinins were unusually potent—that is, effective in high dilution. Probably the commonest error in grouping is failure to recognize persons of Groups A<sub>2</sub> and A<sub>2</sub>B because of the low agglutinability of cells containing the A<sub>2</sub> substance. Weak anti-A serums may fail to cause any agglutination of such cells even when unusually sensitive techniques are used; consequently, such persons would be mistakenly allocated in Group O or B, and under certain conditions accidents would be expected whether these persons donated or received blood that was actually incompatible.

But in addition to such intergroup causes of reactions, there have been reports of post-transfusion reactions when bloods of homologous groups have been transfused, and when the preliminary tests have been made by experienced observers using potent serums.<sup>3,4</sup> Reactions under such circumstances have usually occurred in patients who have had repeated transfusions, the first or first few having been uneventful; such reactions have also been observed with unusual frequency following primary transfusions given to pregnant or post-partum women.<sup>5-10</sup> Some recent disclosures coupled with long-known facts afford a plausible explanation of these intragroup incompatibilities. It is the purpose of this review to consider the probable mechanism, which is based on isoimmunization with certain antigenic components of human blood.

## ISOIMMUNIZATION

Isoimmunization was successfully accomplished by Ehrlich and Morgenroth<sup>11</sup> as early as 1900. Isohemolysins were readily produced in the goat

by injecting erythrocytes of other goats. These immune, not normal, isoantibodies hemolyzed the cells from the goats that furnished the original inoculum and the cells of some, but not all, other goats. The serum did not contain an autolysin—it did not affect or combine with the cells of the animal in which the antibody was formed. These observations were of basic significance in that they showed the possibility that a considerable number of different antigens might exist in similar cells of different individuals in a single species. They also indicated that an animal will not produce antibodies to antigens that are present in his own blood. This principle was expressed concisely by Ehrlich and Morgenroth<sup>11</sup> in the phrase *horrer autotoxicus*. It is true that an animal can form antibodies against some of his own proteins or other components of his tissues, for example, the substance of the crystalline lens, casein<sup>12</sup> and an alcoholic extract of brain,<sup>13</sup> but these materials are blood-foreign and thus satisfy one of the primary prerequisites for antigenicity. The preliminary report by Kidd and Friedewald<sup>14</sup> on a natural antibody found in adult rabbits is of interest. This thermolabile antibody, not present in young rabbits, fixed complement strongly in the presence of saline extracts of normal tissues from a rabbit, rat, mouse, guinea pig or chicken. Extracts of liver and kidney were especially rich in the reactive substance. Immune isoantibodies have been produced in other animals and fowls (Wiener<sup>15</sup>).

## GROUP-SUBSTANCES A, B AND O AS ISOANTIGENS

Isoimmunization in man cannot, of course, be studied with the delicate and thorough experimentation permissible in animals, and observations must perforce be limited to cases of inadvertent mistakes in transfusion and to events that may follow or accompany pregnancy when the parents present certain incompatibilities of their bloods. Thomsen<sup>16</sup> did attempt to immunize men by intramuscular injections of incompatible blood, but no significant rise in isoagglutinating titer was observed (one should note the findings of Biancalana and Tenet,<sup>10</sup> however). This apparent evidence against the isoantigenicity of the

\*All articles in this series will be published in book form, the content volume is *Medical Progress: Annual, 1940* (Springfield, Illinois: Charles C. Thomas Company, 1941. \$4.00).

A and B group-substances is, however, outweighed by the positive evidences mentioned below. Thomsen's negative result is probably attributable to the relatively small quantity of blood injected. Possibly, the route of injection had some influence; as an analogy, the report that rabbits treated with suspensions of streptococci produce anti-C much more readily following intravenous than subcutaneous injections<sup>17</sup> may be mentioned.

It is highly probable that the case reported by Thalhimier<sup>18</sup> in 1921 is an example of the isoantigenicity of Group-Substance B. A boy received 300 cc. of his father's blood; cross-matching had revealed no incompatibility, and only a mild febrile reaction ensued. Eighteen days later, without further tests, the father again served as donor; an alarming reaction stopped the transfusion after 150 cc. of blood had been introduced. Subsequently, the bloods were grouped; the son was found to be an O and the father a B. Although no agglutinative titers were determined, one may surmise with confidence that the anti-B normally present in Group O plasma (with anti-A) was too weak to be detected by the ordinary test, and that the primary transfusion of Group B blood served as an immunizing stimulus leading to a probably marked rise in the titer of anti-B, which thus intensified the incompatibility.

Further evidence that A and B are isoantigenic appears in Jonsson's<sup>19</sup> finding that the maternal isohemagglutinins  $\alpha$  and  $\beta$  are of higher titer when the corresponding antigen, A or B (not present in the mother's blood), is present in the blood of the fetus than when it is absent (transplacental isoimmunization).

Rø<sup>20</sup> observed the development of immune anti-A agglutinins in a Group O patient given Group A blood. Wiener<sup>21</sup> has recorded 2 cases in which powerful immune anti-B (sixteen times the average titer) was produced; the recipients were O and A, the donors B and AB. Another recent case of isoimmunization of a Group B patient given AB blood is also described in detail. The anti-A titer rose from 1:4 immediately after the transfusion to 1:512 on the eighth day. There was no significant difference in titer whether the tests were done at 37°C. or in the icebox, whereas natural isoantibody as a rule reacts more strongly at low temperature. Prior to this report, the only case of isoimmunity involving these subgroups was the weak "irregular" ( $\alpha_2$ ) agglutinin found by Landsteiner, Levine and Janes<sup>22</sup> to have developed, or more probably to have increased in titer, following intragroup transfusions. It was slightly less active at 37°C. than at room temperature. A second transfusion from the same donor

was not followed by symptoms, although the agglutinin was present after the first transfusion.

Davidsohn<sup>23</sup> has argued logically, principally from circumstantial evidence, that the subdivisions of Groups A and AB—the Subgroups  $A_1$ ,  $A_2$ ,  $A_1B$  and  $A_2B$ —are probably significant in causing some post-transfusion reactions, but direct support of this possible mechanism was lacking until Wiener's<sup>21</sup> report appeared last June.

Wiener has thoroughly analyzed a case of isoimmunization of an  $A_2$  recipient by transfusion of  $A_1$  blood. The  $\alpha_1$  behaved like a "cold" agglutinin. In another case,  $\alpha_1$  antibody was considered to have developed in an  $A_2$  woman as a result of isoimmunization by an  $A_1$  fetus in utero, the general explanation first proffered by Levine and Stetson<sup>5</sup> as the mechanism of reactions following primary intragroup transfusions given intra partum or post partum.

Since these are the only cases of this kind on record, it is clear that these subgroups play a very minor role in transfusion reactions. This is because the vast majority of bloods of Groups A and AB contain neither  $\alpha_1$  nor  $\alpha_2$ , and when present the latter are of low potency and are mostly active at low temperature. It seems likely that  $A_1$  and  $A_2$  are feeble isoantigens and produce immune isoantibody only in the rare persons who have some preformed  $\alpha_1$  or  $\alpha_2$ . The observations add to the evidence that the difference between  $A_1$  and  $A_2$  is qualitative. Although dangerous reactions are not likely to occur, it is desirable to use donors of homologous subgroups, that inapparent hemolysis may not deprive the recipient of the benefit of his transfusion.

The formation of anti-O isoagglutinin (probably the same as  $\alpha_2$ ) in low titer has been observed in a Group  $A_1B$  patient.<sup>24</sup> The transfused O cells disappeared rapidly from circulation, although the second transfusion of 300 cc. of O blood produced no symptoms.

#### TYPE-SUBSTANCES M, N AND P AS ISOANTIGENS

Normal isoantibodies for N have never been found; in only 4 cases among several hundreds of thousands of individuals tested has anti-M been detected.<sup>21, 25</sup> Although these three substances, especially M and N, are definitely antigenic in rabbits and other animals, they do not appear to incite the formation of antibody in man. With the exception of a single unconvincing report by Martinet,<sup>27</sup> Type N blood injected into Type M persons, or vice versa, does not produce type-specific isoantibody. Regarding substance P, for which it is difficult to produce immune serums in rabbits, one case is recorded<sup>4</sup> in which an intragroup

(A) transfusion resulted in the development of agglutinins for the donor's blood and for many others of Group A. Further tests revealed that agglutinin P was specifically affected by this isoantibody.

#### RH AS AN ISOANTIGEN

Last year, Landsteiner and Wiener<sup>28</sup> described an additional agglutinable substance in human blood that was recognized by its reactions with antiserum to rhesus (*Macaca mulatta*?) blood (hence termed "Rh"). This substance is common, being present in about 85 per cent of the population. Shortly after this discovery, Wiener and Peters<sup>4</sup> studied the bloods of 3 patients who had had hemolytic reactions, one fatal, after repeated transfusions of correctly grouped blood. The serums of these patients contained abnormal isoagglutinins reacting independently of the regular groups and corresponding to the property Rh, their blood cells did not contain Rh. Thus, the conditions for isoimmunization were present. The authors summarize their second case, in the light of the serologic findings, as follows:

A patient, group A (Rh-) was given a series of blood transfusions from two donors: one group A (Rh+), the other group A (Rh-). The first transfusion from the donor A (Rh+) gave rise only to a subclinical reaction. The following two transfusions from donor A (Rh-) were perfectly compatible so that the donor's cells could be demonstrated in the circulation of the patient (with the aid of the M-N test) for a long time afterwards. On the other hand, the blood from the first transfusion was gradually hemolyzed and eliminated, this being accompanied by the appearance of Rh antibodies in the patient's plasma. Later, when a second transfusion of blood from the first donor, A (Rh+), was given a hemolytic reaction followed. The long interval between the two transfusions from this donor probably allowed time for a fall in the titer of the anti Rh agglutinins so that these were not demonstrable either by the hanging drop or centrifuge technique before the last transfusion. The reason why the Rh agglutinins were not demonstrable immediately after transfusion is that they had been completely absorbed by the Rh+ blood introduced into the recipient's circulation. By the fourth day however, the antibodies had reformed in sufficient amount to be detectable.

Rh+ persons, being about six times as common as Rh-, are that much likelier to serve as donors. The conditions offering an opportunity for isoimmunization would obviously be the transfusion of Rh+ blood into an Rh- recipient. Such transfusions, if primary, would not be expected to result in reactions because normal anti Rh, which might be present in Rh- persons, has not been found, so, as with M and N, the factor Rh can ordinarily be disregarded in the selection of donors for primary transfusions. But an important ex-

ception must be well noted. The intragroup reaction reported by Levine and Stetson<sup>29</sup> led them to suggest the ingenious explanation that the fetus in utero is the source of an antigen, foreign to the mother, that gives rise to the production of an isoantibody capable of mediating a reaction to a transfusion of unsuitable blood given during or shortly after pregnancy. In these cases, as well as in repeatedly transfused patients, it has almost invariably been found by Wiener, Levine and their co-workers that the substance Rh is the antigen responsible, the reacting subjects being Rh-.

In such a pregnancy, the usual conditions are that the woman is Rh-, the husband Rh+, and the fetus has inherited the Rh factor from its father. During pregnancy, some Rh antigen from fetal blood (it appears to be absent from other tissues<sup>29</sup>) reaches the maternal circulation from time to time, perhaps through some placental defect, and incites the production of anti Rh. If the need for transfusion arises, the husband is often selected as donor, he is Rh+ (as are 85 per cent of donors, on the average), and the stage is accordingly set for a hemolytic reaction, which may be fatal. Cross matching of the bloods by the usual technique may not reveal the incompatibility, and even with the more delicate methods to be described, agglutination may escape detection.<sup>30</sup> Obviously, under these circumstances, and, in general, when one is dealing with patients who have received repeated transfusions, it is prudent to use Rh- donors.

#### ERYTHROBLASTOSIS FOETALIS

Strong corroborative evidence that Rh is an isoantigen of great clinical significance has been furnished by Levine and his collaborators. Levine and Katzin<sup>31</sup> observed that intragroup post transfusion reactions connected with pregnancy occurred especially in women whose obstetric histories disclosed an unusually high frequency of toxemias, miscarriages and stillbirths. Are these accidents correlated with the presence of irregular antibodies? Studies of erythroblastosis foetalis by Levine, Katzin and Burnham<sup>32</sup> furnished support for this speculation, 6 of 7 mothers possessed irregular agglutinin corresponding in specificity to anti Rh. Thus, the pathogenesis of the disease depends on isoimmunization of the mother against blood factors of fetal derivation and the subsequent transplacental passage of the maternal isoantibodies that cause destruction of fetal blood, accompanied by compensatory hematopoiesis.

The predominant role of the Rh antigen is shown in Table 1, which reveals an extraordinarily

high incidence of Rh- in the group of selected mothers, and of Rh+ among the husbands and affected children in these families.<sup>32</sup>

Further evidence of the correctness of the explanation proposed is that a large proportion of the mothers of erythroblastotic infants possess anti-Rh of sufficient strength to be demonstrable *in vitro*. The proportion diminishes with the lapse

TABLE 1. *Tests Made with Human Anti-Rh Serums.*

SUBJECTS	Rht +	Rht -
	%	%
1035 persons (general population)	86	14
153 mothers of infants with erythroblastosis	8	92
89 husbands of Rh- mothers	100	0
76 infants with erythroblastosis	99	1

of time after pregnancy—that is, as the period of antigenic stimulation becomes more remote.<sup>29</sup>

In some families, all pregnancies, except perhaps the first, yield infants with erythroblastosis; in others, some of the offspring are normal. Genetically, this difference could depend on whether the Rh property of the father is homozygous or heterozygous. According to Landsteiner and Wiener,<sup>33</sup> the property is inherited as a mendelian dominant and its absence is recessive.\* Half the offspring of a heterozygous (Rh+, Rh-) father would be Rh- and thus incapable of immunizing the mother, but if he is homozygous (Rh+, Rh+), all pregnancies will afford an opportunity for the production of anti-Rh. If the first infant is unaffected, it may be because a single pregnancy sometimes does not afford a sufficient stimulus for adequate immunization. Doubtless, mothers as well as transfused patients vary a great deal in the degree of their isoimmunizability as well as in its selectiveness, as the response of animals to heteroantigens does.<sup>36</sup>

Rh- blood is better for transfusing erythroblastotic infants<sup>29, 35</sup>; however, the mother's blood should not be used, since it probably contains anti-Rh. Theoretically, the mother's colostrum might contain a relatively high concentration of isoantibody; perhaps early nursing by the mother should be forbidden.<sup>37</sup>

To explain the few cases of erythroblastosis in Rh+ mothers, one may reasonably assume that

\*The hereditary nature of the Rh factor permits its use in cases of disputed parentage, but only when both mother and alleged father are Rh-, which occurs only once in forty nine times on the average, so that exclusions based on this factor are rare. However, one has already been found.<sup>34</sup> The putative father and the mother were Rh-, and the child was Rh+. Curiously, —a gross and shameful waste of exclusive evidence,—there was triple proof of nonpaternity (the falsely accused man belonged to Group B, the mother to Subgroup A<sub>2</sub>B, and the child to Subgroup A<sub>1</sub>B, furthermore, the man and woman were Type M and the child was MN).

Levine,<sup>38</sup> Javert<sup>39</sup> and Katzin<sup>40</sup> have found another atypical agglutinin in an Rh- mother of an erythroblastotic infant. It reacted mainly with a particular anti-Rh serum. Consequently, the substance detected by this agglutinin may perhaps be genetically related to Rh.

the same general mechanism is operating but that a different isoantigen is concerned. Antigenic components other than those already mentioned are known to exist in the red cells, and there is no reason to think that still more may not be discovered in the future.

Concerning this particular isoimmunologic disease, such antigens should not be sought in other tissues or fluids if interpretation of past lessons is correct. An early hypothesis was that if a Group B or Group O mother was carrying a Group A child, the mother's  $\alpha$  antibody might penetrate the placenta and cause destruction of fetal erythrocytes.<sup>38</sup> However, it could not be shown that such incompatibilities bore any relation to the disease, and it is now known that in most persons the substances A and B are present not only in the erythrocytes but also in various tissue cells and that they are dissolved in various secretions, including the amniotic fluid. This wide distribution allows neutralization of the isoantibodies and serves to protect the fetal red cells. Possibly, those who do not secrete such substances would be less well protected.

An explanation offered by Darrow<sup>39</sup>—that icteric symptoms might be due to an isoimmunity involving differences between maternal and fetal hemoglobins—has not been substantiated. There is, however, a recent report<sup>40</sup> that such antigenic differences do exist and that fetal hemoglobin is more complex than the adult kind; that is, the precipitins in an antiserum for adult hemoglobin are completely absorbed by either antigen, but antiserum for fetal hemoglobin still reacts with the homologous antigen after the precipitins for adult hemoglobin have been completely removed.

#### EXTRACELLULAR ISOANTIGENS

There has long been considerable speculation<sup>41</sup> about the possibility that incompatibilities may not be restricted to differences between the cellular elements of the blood and the corresponding iso-hemagglutinins or lysins. A few observations suggest that there may be sufficient isoantigenic differences between the proteins of plasma so that, under appropriate conditions, isoprecipitins or sensitizing antibodies may be formed and may be instrumental in producing allergic shock. In 1916, Marie reported two cases of serum sickness in typhoid patients following a second injection of human serum from typhoid convalescents.<sup>41</sup> Urticarial reactions after transfusions have been described by many authors and are commoner and, usually, severer after repeated transfusions, especially if the same donor is used. Böttner<sup>42</sup> and Traut<sup>43</sup> have discussed this anaphylactic aspect

of the problem Gyorgy and Witebsky<sup>14</sup> observed a patient who, at intervals of several days, was given a transfusion from the father, a second from the mother, and a third from the father. Symptoms of severe shock after the third transfusion were relieved by epinephrin. The patient's skin reacted to the father's but not to the mother's serum, and the patient's serum fixed complement in the presence of the father's serum but not of the mother's. A similar case of selective cutaneous reactivity is reported by Wiener et al.<sup>14</sup>

#### TECHNICAL CONSIDERATIONS

From the foregoing review, it is obvious that unusually careful precautions must be taken when one is testing for compatibility prior to transfusing pregnant and recently delivered women or any patients who have received previous transfusions. Immune isoantibodies may remain in the circulation for only a few weeks<sup>7</sup> or for more than a year.<sup>29</sup> Wiener and Forer<sup>30</sup> give an example of how extremely complicated the selection of a compatible donor may be. A woman had had chills, fever and jaundice following two transfusions. She belonged to Group O, but her serum agglutinated the cells of each of 28 Group O persons tested. Besides the normal anti A and anti B in her serum, there were two abnormal agglutinins, anti Rh and anti M. The patient was Rh- and Type N, as would be expected. Inasmuch as one person in five is Type N and one in seven Rh-, it is to be expected that one in thirty-five persons will be N Rh-. Among 90 Group O donors tested, 2 were found to be ON Rh-. Their bloods did not cause any reaction when transfused into this patient, who entirely recovered.

The necessity of having highly potent serums available for purposes of grouping bloods has been sufficiently stressed.<sup>4,18</sup> It is also apparent that the so-called "universal" donor\* does not exist. Even an O Rh- blood containing weak  $\alpha$  and  $\beta$  antibodies cannot be safely used in the rare A and A<sub>1</sub>B recipients whose serums contain anti O ( $\alpha$ ). Considerable difficulty has been experienced in obtaining useful anti Rh serums, which have been derived from rabbits immunized with rhesus blood,<sup>28</sup> from human beings accidentally immunized,<sup>29</sup> and, very recently, from guinea pigs

injected with rhesus blood.<sup>33</sup> The specific reactivities of different serums are usually but not invariably parallel.<sup>43</sup> This complication may tentatively be ascribed to the existence of subgroups such as Rh<sub>1</sub> and Rh<sub>2</sub>. Anti Rh serums also differ in the thermal range of their activities. Some have the property of so-called "cold" and others of "warm" agglutinins. It would be safest to run tests in triplicate, one in the icebox, one at room temperature, and one at 37°C. For the last, thirty minutes' incubation followed by centrifugation for one minute at 500 r.p.m. is recommended. If, on resuspension of the sediment, no gross agglutination is apparent, the preparation should be examined microscopically.<sup>51</sup>

Technics and general precautions have recently been described in full.<sup>4,18</sup> Inasmuch as the irregular isoagglutinative reactions are much weaker in intensity than those produced by anti A and anti B or anti M and anti N, it is desirable to use the most sensitive technics possible. Lund's<sup>52</sup> experiments with the regular isogglutinins show that a noteworthy refinement can be achieved by diminishing the concentration of cells and increasing the quantity of serum used in the test, thus allowing more antibody for each erythrocyte. The usual concentration of cells recommended, 1 to 2 per cent, was found to be excessive and relatively insensitive. A concentration of about 0.06 per cent was eight times as sensitive as one of 0.5 or 10 per cent. Concentrations less than 0.007 per cent were thirty-two times as sensitive. Use of these low concentrations involves centrifugation and secondary reduction of the volume of supernatant to secure a suitably dense suspension for microscopic examination.

The quality of agglutination in the Rh system is peculiar, being reminiscent of the floccular rather than the granular type observed in bacterial agglutination. Wiener<sup>37</sup> thinks that the Rh antigen may be located partly below the surface of the cell whereas A, B, M and N are superficially located antigens. A new so-called "sedimentative" technic has just been described by Landsteiner and Wiener.<sup>33</sup> Because of the importance of the Rh antigen and the need of further work designed to facilitate its detection, this procedure is described in full.

For the production of the sera large guinea pigs were injected intraperitoneally with a suspension of washed red cells of rhesus monkeys, each animal receiving a dose corresponding to 1 cc. in later experiments to 2 cc. of whole blood. The injection was repeated after five days, and one week later the animals were bled. The sera of the majority of animals were found to show a difference between the two sorts of blood, Rh+ and Rh-, and in a group of ten animals

\*A method of rendering human donors blood serifer by neutralization of  $\alpha$  and  $\beta$  has been proposed by Wiener and Landsteiner.<sup>34</sup> The addition of a few ml. of the oil of A and B still leaves 500 cc. of supernatant blood sufficient to reduce the agglutinating capacity to very low levels. This is satisfactory altogether. These workers state that 0.5 or 100 ml. of neutralized Group O blood have been given mainly to patients belonging to the other three groups with satisfactory clinical results. A few cross reactions were sometimes met with. If the expense of isolating the group substances is not too great, this method may have some usefulness, but it does not remove the need for careful precautions in the serum transfusions chiefly discussed in the present review, and it does not reduce the danger of transfusing Group O blood into the occasional recipient of Group A or A<sub>1</sub>B who has anti O agglutinins.

usually one or more were found that yielded sera suitable for practical diagnosis. The manner of selecting the sera is given below.

While in the case of the immune rabbit sera the reagent was prepared in the customary way by absorbing the diluted serum with negatively reacting blood, it was found with several guinea pig sera that absorption with human blood resulted merely in a non-specific diminution of the agglutinin content, no matter whether positive or negative blood was used. This led us to test the effect of simple dilution, and indeed it was found that a distinction between positive and negative bloods could be made directly without absorbing sera. (As an analogy, mention may be made of rabbit immune anti-A sera which cannot be specifically absorbed with A<sub>2</sub> cells to produce a reagent for A<sub>1</sub>, absorption with A<sub>2</sub> blood serving merely to diminish the agglutinin titer.)

The method for determining suitable sera consists in making serial dilutions by halves and testing with known negative and positive blood. Those sera which show in three (or more) successive dilutions negative reactions with the former and positive ones with the latter blood are usable.

The actual tests can usually be carried out simply by selecting a dilution of the serum, e.g., 1:10, which gives no reactions with negative but definite reactions with positive bloods, those sera that contain appreciable amounts of anti-A or anti-B agglutinins having been

to 1 hour, by direct inspection of the bases of the tubes, with a hand lens. Negatively reacting bloods then show a circular deposit with a smooth edge, while positive bloods have a wrinkled sediment with a serrated border or show a granular deposit [Fig. 1]. From these readings, as a rule, the diagnosis can readily be made. The readings are facilitated by using racks having small holes beneath the bottom of the tubes. Following the reading the tubes are shaken and the sediment examined after it forms again. A further examination is made after 2 hours, again inspecting the sediment. The tubes are then gently shaken and the suspension is examined microscopically: the negative blood samples are mostly perfectly homogeneous; the positive ones show various degrees of agglutination, not infrequently visible to the naked eye. At times, the clumping is quite weak in spite of a distinctly positive sediment picture. Needless to say, positive and negative control bloods should be included in each test.

As already mentioned, with the great majority of specimens the distinction between positive and negative reactions is quite definite but the positive reactions vary in strength and some bloods offer difficulties because of their weak reactions. However, after sufficient practice, and by repeating the tests if necessary with fresh blood samples and several sera, only in some few instances were the reactions questionable. Marked differences in the intensity of the reactions were also observed in tests made with human anti-Rh sera.

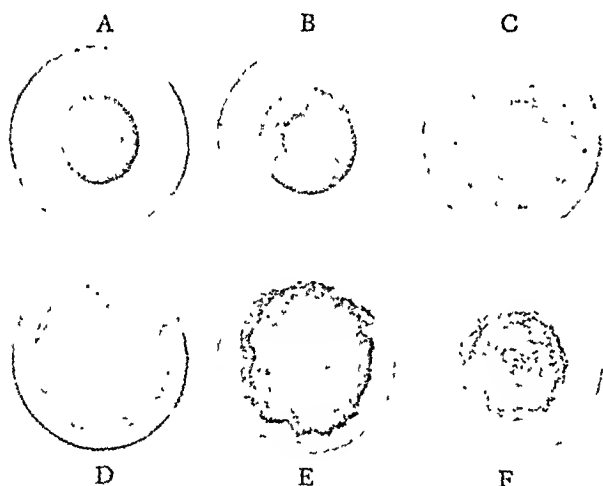

FIGURE 1. Appearance of Sediments in Bottoms of Tubes. (Reproduced from Landsteiner and Wiener<sup>33</sup> with permission of the publisher.)

A and B are negative reactions, the inner light disk of the latter being due to a slight convexity in the bottom of the tube; C is a faintly positive reaction; D is a weak reaction; E and F are positive reactions.

previously absorbed with small quantities of A and B blood. Since the sera are used diluted, inactivation is mostly unnecessary. The blood to be tested should be fresh.

Another method, alternative to dilution alone, is to absorb the sera diluted, e.g., 1:4 with a quantity of blood (using A or B cells if indicated) sufficient to remove the reaction with Rh-negative blood.

Two drops (0.1 cc.) of the test fluid are then mixed with one drop of 2 per cent (in terms of blood sediment) washed blood suspension, freshly prepared, in a narrow tube of 7 mm. diameter and allowed to stand at room temperature. Readings are taken after sedimentation has occurred, usually after 30 minutes

## CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED  
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

### CASE 27481

#### PRESENTATION OF CASE

A fifty-three-year-old housewife was admitted to the hospital because of jaundice, dark urine and light stools.

About six months before entry, the patient noted the gradual onset of a feeling of "exhaustion," which persisted. Previously, she had been in good health. At about this time, following a "bad cold," she noticed a yellowish tint to the skin. She then began to have from three to five loose bowel movements each day; no blood was passed, however. The patient gradually lost appetite. About seven or eight weeks before entry, there was occasional nausea and vomiting of yellowish material. About a week later, she noticed that her urine became darker and her stools became "putty-like." Her former diarrhea had been replaced by constipation. At about this time, she noted that her skin had again become yellow. From then on, the jaundice continued to deepen. Once, while vomiting, the patient put her hand on the upper part of her abdomen, and became aware of tenderness toward the right side. There was, however, no spontaneous pain until the last few days before entry, when there was a dull ache in the back over the spine of the right scapula. About a week before entry, the patient had some sweating at night, associated with bitemporal headache. She had no chills. On one occasion her temperature was 102°F.

The family and past histories were not of importance. A year before admission to the hospital, a boy boarding at the patient's house developed typhoid fever. Specimens of the patient's blood, urine and stools were therefore examined by the State Laboratory. She was found to be a typhoid carrier, and was obliged to give up her boarding clients.

On admission, the patient was very obese, but was in no acute distress. The skin and scleras were moderately jaundiced. The heart and lungs were not remarkable. The abdomen was obese, with voluntary spasm and tenderness to deep pressure over the upper portion, more marked toward the right. A poorly defined mass was palpable in the right upper quadrant.

The temperature was 101°F., the pulse 95, and the respirations 22. The blood pressure was 96 systolic, 50 diastolic.

Examination of the blood showed a red-cell count of 5,520,000, and a white-cell count of 9200 with 82 per cent polymorphonuclears. The serum contained 9.6 mg. bilirubin per 100 cc., with a diphasic van den Bergh reaction. The serum protein was 6.6 gm. per 100 cc. The prothrombin time was 31 seconds (against a normal of 22 seconds). The hematocrit was 46.8 per cent. The blood Hinton reaction was negative.

The urine showed a ++ test for albumin, with occasional clumps of red and white cells in the bile-stained sediment; it was sterile on culture. The stools showed no pathogens in five successive cultures; on one occasion, an "atypical" colon bacillus was isolated.

The patient was given repeated venoclyses of glucose solution. After the first few days, her temperature remained normal. On the twelfth hospital day, duodenal drainage yielded a small amount of fluid with a bulky sediment that contained numerous red blood cells, occasional clumps of white blood cells and occasional clumps of calcium bilirubinate crystals. There were no cholesterol crystals.

On the thirteenth hospital day, an operation was performed.

#### DIFFERENTIAL DIAGNOSIS

DR. WYMAN RICHARDSON: "She noticed a yellowish tint to the skin." This is important. The question is whether or not there was real jaundice at this time. As we know, patients frequently complain of a yellowish tint that is not due to jaundice. However, in view of the fact that the patient did develop jaundice later, it is perhaps significant in this story.

I might say that I do not see why an operation was performed on this patient in the light of the evidence given here. Realizing that it is very difficult to make these summaries in a brief form, however, I should like to say that one of the easiest tests to perform is that of looking at a stool. As a matter of fact, such a test is one of the hardest things to get done in a hospital. These stools were all sent off and cultured. Whether anyone looked at them, I do not know. I should like very much to know whether the stools were brown or gray.

DR. TRACY B. MALLORY: It is reported that the stools were tan colored.

DR. RICHARDSON: That means to me that some bile was getting through the gastrointestinal tract.

One other thing about the operation: in these

exercises, an operation sometimes includes a peritoneoscopy, so that this patient was not necessarily operated on with the idea of some very radical procedure.

The first question to decide, if possible, is, of course, whether a case of this sort represents intrahepatic disease or an obstruction of the major bile ducts. I believe that the evidence is more in favor of intrahepatic disease than of biliary obstruction. If this had been a case of tumor located at the ampulla or thereabouts, one would expect a progressive increase in the jaundice, which might wax and wane but which should, on the whole, be progressive. Obstruction characteristically produces a severe jaundice frequently associated with severe itching. This jaundice was described by the examiner as moderate, and the van den Bergh reaction corroborates the fact that, although fairly marked, it was not the very severe type that would be seen in complete biliary obstruction. Furthermore, obstruction of the bile ducts by tumor is rarely associated with a febrile reaction, so that I do not believe that this patient had tumor of the biliary tract.

Infection of the biliary tract might account for the fever this patient had; it was not typical of cholangitis, however. A Charcot fever is often associated with real chills. Usually, it runs a short course, and one would not expect it to be relieved by intravenous glucose. That last statement, however, may not be true: the subsidence of fever may not have been due to the administration of glucose; it may have been a coincidence.

The problem of the mass in the right upper quadrant comes into the picture at this point. The abdomen was obese, and the mass poorly defined. Taking these two statements together, in discussing this case, I shall have to assume that there was no mass. The examiner seems not to have been very certain of it. If there was a definite mass, the examiner might have thought that it represented the gall bladder, and an enlarged gall bladder would be, perhaps, slight evidence against the presence of gallstones, according to Courvoisier's law, although that does not hold very much more often than in half the cases. The mass, if there was a mass, might represent some form of tumor in that region and might lend weight to a diagnosis of neoplastic disease. On the whole, the evidence is against an obstruction of the biliary tract, especially low down.

I want to bring up three possibilities, which I wish to discard. The first is the question whether this patient might have had ulcerative colitis, accounting for the diarrhea, because we have seen

some patients with ulcerative colitis who developed degenerative liver disease. The cases that I have seen have occurred in patients who had very severe ulcerative colitis and obviously were very ill, whereas this patient, if she had ulcerative colitis, was not sufficiently sick to lead anyone to suspect it and to look for it; so that I think such a diagnosis is unlikely. The question of amebic dysentery comes to mind because of diarrhea and fever, and I wonder if amebic abscesses could produce this degree of jaundice. I think that perhaps they might, but I do not quite see how they could unless there was very extensive disease of the liver. We might just as well rule that out. There is no way of proving it unless the amebas were discovered, and I assumed that they were not looked for. Finally, what bearing did the typhoid bacillus in the biliary tract have on this patient's illness? I must confess that my knowledge of typhoid infection is very slight. Back in 1923, at the time of my first contact with this hospital, we saw four or five cases of typhoid fever during a period of service. I do not recall seeing a case for the past five years. However, if a patient is living with the typhoid bacillus in the biliary tract he would be less likely to have generalized infection as a result of it, having acquired this symbiotic relation. Whether the presence of these bacilli is likely to result in the formation of stones, I am not certain, in spite of the textbooks. On the whole, I believe that the presence of the typhoid bacillus and the fact that the patient was a carrier are probably red herrings in this case.

So far as cholangitis is concerned, I have never been quite sure what cholangitis represents. I gather that it is an infection of the biliary tract that results in jaundice and infection, may be associated with small abscesses in the liver, and may eventually result in a biliary cirrhosis, if the patient does not die first. One should consider cholangitis in this case, but I do not see any suggestion of cholangitis unless we assume that there was obstruction, possibly due to stone, which I have been inclined to rule out. Acute cholecystitis might have been considered, but we must account for jaundice by an acute empyema or infection of the gall bladder. If that were so, we should have to assume that the patient had a stone in the common duct as well as in the cystic duct. Furthermore, I again bring up the fact that the fever apparently subsided after intravenous glucose therapy.

Then, the question of an intrahepatic disease comes up, and I briefly note the patient's symp-

toms. She had a feeling of exhaustion and what was called a cold. She had some apparent infection, followed by diarrhea, then jaundice and fever, with very little pain. It seems to me, taking the whole picture together, that the most likely diagnosis is a toxic hepatitis, with some degeneration or even destruction of the liver associated with fever; when treated in the hospital with glucose, the process might have been held in abeyance.

I should like to emphasize one other point: the blood smear. The patient had a white-cell count of 9000, with 82 per cent polymorphonuclears; this would be consistent with some sort of infection. There was apparently a reduced number of lymphocytes—they must have been less than 18 per cent. If monocytes had been present, there might have been less than 10 per cent, and reduction of lymphocytes could be associated with some lymphoid tumor: lymphoma or Hodgkin's disease of some type. I consider that poor evidence to bring up in favor of lymphoma.

The decision what to do with a patient with jaundice often depends on the course. Here again, I have a right to be a little "peevish" because I do not know the course during the twelve days under treatment, but one gets the impression that the patient was improved. We know that the temperature came down. We do not know whether the jaundice decreased or remained the same. Duodenal drainage was done, but the color of the aspirated fluid is doubtful. I do not know whether calcium bilirubinate crystals are sufficient to give bile color, and shall not take the time to talk about it. I do not consider it important because we have the stool examination. The finding of cholesterol crystals in the bile or the finding of a considerable amount of cholesterol crystals in the duodenal drainage has been considered evidence of gallstones. I am not sure that calcium bilirubinate crystals have the same significance, and on the whole I discard that finding.

To summarize, it seems to me that the course of this disease is that of a toxic hepatitis. I believe that this progressed to a serious degree of actual liver degeneration, and that when this patient was operated on some evidence of a toxic cirrhosis or fibrosis of the liver was found. The operation, I hope, was a peritoneoscopy, because that procedure, in my opinion, might have made a radical operation unnecessary. It is only fair to say that I should assume that the patient, before being operated on radically, would have had more study of the gastrointestinal tract by x-ray or otherwise. She may have been under mosquito bars, and they may not have wanted to take her down to the x-ray room. One other thing: it is true that cholecystectomy has often resulted in the

elimination of typhoid bacilli from the stools of carriers, but I assume that this patient was much too sick for operation, on that basis, to be considered.

A PHYSICIAN: How do you explain the blood in the duodenal drainage?

DR. RICHARDSON: I might have mentioned that; I considered it quite carefully. One can find numerous red cells from the trauma of passing the tube. We frequently get positive guaiac tests following gastric analysis without a lesion, and therefore I did not believe that one need account for red cells on the basis of an ulcerative lesion. There may have been a bleeding tendency because of a slightly increased prothrombin time.

DR. ALLEN G. BRAILEY: A toxic hepatitis might perfectly well have followed a stone in the common duct with partial obstruction.

DR. MURRAY COPELAND: I have seen jaundice in association with cholecystitis and no stone.

DR. RICHARDSON: Due to cholangitis, I suppose.

#### CLINICAL DIAGNOSES

Obstructive jaundice.

Typhoid cholecystitis.

#### DR. RICHARDSON'S DIAGNOSIS

Toxic hepatitis, with secondary cirrhosis of the liver.

#### ANATOMICAL DIAGNOSES

Colloid carcinoma of gall bladder, with direct extension to common and cystic bile ducts, liver and pancreas, and with metastases to peritoneum, ovary, mesenteric and retroperitoneal lymph nodes, mediastinum, kidneys, lung, liver, pleura and thoracic duct.

Icterus.

Ascites.

Hydrothorax, slight.

Chronic vascular nephritis, slight.

Endometrial polyp.

Obesity.

#### PATHOLOGICAL DISCUSSION

DR. MALLORY: I think one's attitude to the case must depend on how seriously one takes the mass in the right upper quadrant, which certainly was not described in the record as anything very distinct. I gather, however, that the surgeon in charge of the case believed more strongly that there was a mass. At any rate, he decided on an exploratory operation, with the diagnosis of obstruction to the common duct. He did not commit himself as to whether it was due to stone or neoplasm. The abdomen was opened, and an enlarged gall bladder, with walls that were ex-

remely thick and very hard, was found. In spite of prolonged efforts, the surgeon, and he was a competent one, was unable to locate the common duct. He took a piece of tissue from the wall of the gall bladder and backed out. He also aspirated the gall bladder. It contained some colorless fluid, which was sent to the laboratory for culture. The liver appeared grossly normal except for slight enlargement and bile staining. The patient then pursued a rather rapid downhill course and died in approximately three weeks. The biopsy showed carcinoma of the colloid type and at autopsy we found a cancer involving the gall bladder, the extrahepatic and intrahepatic bile ducts and the region of the head of the pancreas. In cases such as this, it is sometimes quite difficult to decide at autopsy where the cancer is primary. The possible foci are the gall bladder itself, the bile ducts and the pancreas. In this case, it seemed quite obvious that the pancreas was secondarily involved. The bile ducts, although completely surrounded by tumor and constricted by external pressure, were not invaded or actually occluded, so that I think we can be fairly confident that this tumor was primary in the gall bladder.

Culture of the gall bladder at the time of autopsy gave a pure culture of typhoid bacillus. Cancer of the gall bladder, we know, almost invariably occurs in patients who have been chronic carriers of gallstones for ten to twenty years. It is the greatest danger of the so-called "silent stone" in the gall bladder. We were therefore surprised to find no gallstones in this case. On the other hand, we have reason to believe that this patient had had a very chronic cholecystitis for many years, owing to the presence of the typhoid organisms. It is at least possible that a typhoid cholecystitis was the long-standing focus of chronic inflammation on which this neoplasm developed. That would be my final interpretation of the case. There was a very slight degree of cholangitis, but the major functional lesion was carcinomatous infiltration around the bile ducts. There were peritoneal implants and also numerous distant metastases.

DR. RICHARDSON: Was any bile getting through?

DR. MALLORY: Bile was still coming down from the liver. It obviously was not passing through the cystic duct, since the bile in the gall bladder was perfectly colorless; however, the bile in the common bile duct and in the hepatic ducts was orange.

For about two years, the patient had suffered from "gallstones," occasionally associated with attacks of colic, and at times with jaundice. On the morning before entry, she did not feel well and soon after eating a piece of candy developed an acute, very severe, right-upper-quadrant pain, which tended to travel "down." A few hours later, she began to vomit, and continued to vomit frequently during the night. The pain was intermittent and, despite medication by her physician, persisted until entry.

Thirteen years before entry, both breasts had been removed for cystic disease, and three years later, an operation on the uterus was performed.

Physical examination showed a well developed and well-nourished, acutely ill woman, who was heavily narcotized. The lips and fingers were cyanotic. There was no icterus. Examination of the chest was negative. The abdomen was moderately distended. There was extreme tenderness, with resistance, across the upper abdomen, and distinct spasm in the right upper quadrant. No masses or organs could be palpated. There was some tenderness below the right costal margin posteriorly and in the right lower quadrant, but it was not so marked as that in the upper abdomen. Peristalsis was heard on only one examination, when there was an occasional rush associated with pain.

The temperature was 99°F, the pulse 105, and the respirations 28. The blood pressure was 120 systolic, 90 diastolic.

Examination of the urine showed a large trace of albumin, a green reaction to Benedict's test and 2 or 3 white cells, many hyaline and granular casts and a few cellular casts per high power field. The blood showed a red-cell count of 5,100,000 with 86 per cent hemoglobin, and a white-cell count of 10,000. A few hours later, the white-cell count was 6000 with 69 per cent polymorphonuclears. There was a decided polymorphonuclear shift to the left, the majority of the neutrophils being young forms with single lobes.

X-ray study of the abdomen showed no evidence of free gas beneath the diaphragm. There was a large amount of gas in the colon and small bowel, but no definitely dilated loops were seen.

The patient's condition rapidly became worse, the temperature rising within a few hours to 103°F. and the pulse to 150. She died nineteen hours after entry.

#### DIFFERENTIAL DIAGNOSIS

DR. RICHARD WARREN: This elderly woman died within forty-eight hours of the onset of an attack of abdominal pain which was so severe that it was uncontrollable by several doses of morphine. This pain was due to some "peritoneal insult" in

#### CASE 27482

##### PRESENTATION OF CASE

A sixty-eight-year-old housewife was admitted in a semistuporous, moribund condition

the upper abdomen, more on the right side than elsewhere. None of the available information is revealing enough to allow me to make a diagnosis that I am confident is correct. Several possible diagnoses suggest themselves, and from these I shall select the one that seems to me the most probable.

The commonest cause of such severe, sudden upper abdominal pain is a perforation of the stomach or duodenum from either ulcer or cancer. There is no history of ulcer or cancer, however (unless one accepts the "gallstone" story as perhaps indicative of one of these), and no subphrenic air was seen by x-ray examination. Moreover, the patient died more rapidly after onset than the usual patient with untreated gastroduodenal perforation.

It is quite certain from the history that the patient had gallstones. The association of jaundice with the attacks of pain supports this very strongly. It is tempting, then, to assume that the terminal episode in the case was some complication of cholelithiasis. The two complications that could give this picture are acute cholecystitis, with perforation, and acute pancreatitis. The former rarely perforates so early in the attack as this, even if complicated by carcinoma of the gall bladder, and is rarely so fulminating. Acute hemorrhagic pancreatitis is a distinct probability. The extreme tenderness across the upper abdomen, the persistent vomiting, the failure of the pain to respond to morphine, the suggestion of tenderness posteriorly and the rapid downhill course all suggest this diagnosis. One would like to see tenderness extending more toward the left upper quadrant than toward the right lower quadrant, but that is not essential.

The only other diagnosis that seems likely is infarction of some intraperitoneal organ, specifically a loop of small intestine. The previous abdominal operation, the abdominal distention, the normal temperature and rising pulse when first seen and, most particularly, the fact that an occasional rush of peristalsis was associated with pain are in favor of this. Against it, however, are the presence of gas in the colon by x-ray examination, and of maximum signs in the upper abdomen at some distance from the abdominal scar and the fact that the physicians in charge did not consider this diagnosis seriously enough to operate.

The only point in the case that makes one somewhat suspicious that the sole diagnosis was pancreatitis is the fact that at two places in the case summary it is intimated that the process tended to

spread to the right lower quadrant. This suggests a leak of some septic or irritating fluid down the right gutter. This is possible in pancreatitis, and may represent fat necrosis. It would, however, be more likely in duodenal or cholecystic perforation.

#### CLINICAL DIAGNOSES

Perforation of gall bladder.  
Peritonitis.  
Acute cholecystitis.

#### DR. WARREN'S DIAGNOSES

Cholelithiasis.  
Acute hemorrhagic pancreatitis?  
Perforation of the gall bladder?

#### ANATOMICAL DIAGNOSES

Acute hemorrhagic pancreatitis.  
Acute aseptic peritonitis.  
Multiple fat necroses.  
Bronchopneumonia.  
Cholecystitis, chronic.  
Cholelithiasis.  
Operative scars: bilateral simple mastectomy; appendectomy; ventral suspension of uterus.

#### PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: Dr. Warren was able quickly to narrow down the differential diagnosis to two possibilities: perforation of the gall bladder and acute hemorrhagic pancreatitis. It is evident that the clinicians on the ward also went through an essentially similar process of reasoning, but as their first choice they picked perforation of the gall bladder. The post-mortem examination proved that Dr. Warren was correct. When the abdominal cavity was opened, considerable amounts of slightly turbid fluid were found in which were numerous droplets of fluid fat. All the peritoneal surfaces were studded with small chalky foci. When the gastrocolic ligament was incised, the anterior surface of the pancreas presented as a swollen, purplish mass. Incision into the organ demonstrated many spots of chalky fat necrosis and also many semiliquid foci of hemorrhagic necrosis. As is almost always so in hemorrhagic pancreatitis, there was a diseased gall bladder. Its walls showed fibrous thickening. It contained turbid fluid with but little color and eighteen small, rather friable gallstones. The hepatic and common bile ducts were normal, and there was no stone at the ampulla. The remainder of the autopsy showed little of interest. There was minimal aortic and coronary sclerosis and bare traces of incipient bronchopneumonia.

## HIDDEN HUNGER

Mass starvation requires time before its full impact is felt. The past winter in Europe, devastating as it must have been, did not produce the degree of physical injury that was feared. Populations might have been in the process of starving, but they had not starved; the fatted calves had been rerouted into Germany, but bellies could still be filled with the husks that the swine had left; epidemics of disease were anticipated, but they did not materialize.

Dr. Harold C. Stuart, of the Harvard School of Public Health, recently spoke to the American Academy of Pediatrics concerning some of his observations in visiting unoccupied France this year. The people there, and particularly the chil-

dren, were not, apparently, so poorly nourished as had been expected; certainly, they were in much better condition than those of Spain, through which country the party had traveled into France. However, in those cases in which vitamin levels of the blood were determined, the significant fact was brought out that these levels were low, occasionally to the point of depletion.

At the same meeting, Surgeon General Thomas Parran, of the United States Public Health Service, elaborated on the distinction between the "hollow hunger" of empty starvation and the "hidden hunger" of vitamin, mineral and protein deficiency. Hollow hunger can be mitigated from time to time by the husks of food with which the belly may be filled; hidden hunger gnaws relentlessly on, sapping the strength, the vitality and the ambition of its victims.

Hidden hunger is the inexpensive, scientific weapon with which Germany can and will hold whole nations in subjection once they have been conquered by the sword. An adequate diet is the weapon with which we, as a nonbelligerent (if not a silent) partner, must make sure that we adequately equip our allies. A country that a few short years ago was ploughing under its wheat, burning its potatoes and killing off its hogs may soon be forced to step up its production and even ration such critically important food supplies as meat, cheese, eggs and milk, that the unconquered democratic countries may maintain their vigor, their initiative and their resistance.

This task and this sacrifice are up to us. We are still living in a land of plenty, but we may yet have to tighten our belts if those nations with which we have thrown in our lot are to achieve eventual victory, or even, perhaps, remain unconquered.

## GOLDEN JUBILEE

ANOTHER milestone in the progress of "quality-milk" production was passed when, on September 17, the Walker-Gordon Farm at Charles River Village, Massachusetts, celebrated its fiftieth an-

niversary. At that time, the World's Fair rotolactor was officially dedicated. A few weeks later, the fiftieth anniversary was further celebrated at the Walker-Gordon Farm at Plainsboro, New Jersey, where the original rotolactor has been in service for several years.

Although certified milk and Walker-Gordon have been associated in our minds for years, so that the terms have seemed almost interchangeable, the two developments, directed toward the same purpose, appeared spontaneously and independently. Walker-Gordon started producing what was probably the world's first really clean milk in 1891 in Massachusetts; Dr. Henry L. Coit, of Newark, New Jersey, conceived the idea of the medical certification of certain dairy farms in 1893, and, the first farm to be so certified was in that state.

The certification of farms physically equipped to produce pure milk and managed by farmers intellectually and morally equipped for its production has been the most powerful motivating force for improvement that the milk industry has ever received. Today, however, certification or noncertification is not so important as the facts that knowledge of the requirements of clean milk production are well known, the way having been shown by certified milk, and that, by and large, the certified farms still fulfill these requirements.

Walker-Gordon Farm, which antedates certification, has long served as a model certified dairy, as well as a research laboratory for the scientific improvement of milk production and the modification of milk for infant feeding. Here, vitamin D milk was first produced on a commercial scale, and many improved methods of laboratory control were developed; at the Plainsboro farm, the forage dehydrator, a conserver of vitamin A, first came into use.

The installation of the rotolactor, making a complete inexorable revolution every ten minutes, with its constant procession of disciplined mammals, furnishes a token that Walker-Gordon is looking forward to another fifty years of progress. Six prize bulls, serving numbers of selected cows by artificial insemination, are a guarantee that good milking stock will be perpetuated.

## MEDICAL EPONYM

### ISLANDS OF LANGERHANS

These structures are described in an inaugural dissertation submitted in candidacy for the degree of Doctor of Medicine from the Friedrich Wilhelm's University at Berlin on February 18, 1869, by Paul Langerhans (1849-1888), entitled "Beiträge zur mikroskopischen Anatomie der Bauchspeicheldrüse [Contributions to the Microscopic Anatomy of the Pancreas]." This monograph was privately printed by Gustav Lange, of Berlin, in 1869. A portion of the translation follows:

These cells are small and irregularly polygonal in form; their contents are quite homogeneous, glistening and without granules; the nuclei are clear, round and of medium size. Their average diameter is from 0.0096 to 0.0120 mm., and that of the nuclei from 0.0075 to 0.0080.

These cells for the most part lie in clumps, peculiarly distributed in the parenchyma of the gland. If a pancreas that has been in Müller's liquid for two or three days is examined under low power, such as No. 4 objective in Hartnack's system, there will be observed regularly scattered in the gland rounded spots stained a deep yellow, about one to a field when a No. 3 ocular is used. Under higher powers, it is evident that these spots consist entirely of our cells. They are heaped up in rounded clumps, regularly distributed in the parenchyma (in the old meaning of the word) of the gland. The clumps have for the most part a diameter of 0.10 to 0.24 mm., and can easily be perceived even in teased preparations made either from fresh glands or from those that have been treated for a short time with iodine serum.

### SECTION OF OBSTETRICS AND GYNECOLOGY\*

#### FATAL LOBAR PNEUMONIA IN PREGNANCY

A thirty-six-year-old primipara who had had no care whatever was seen, when about eight months pregnant, by her family physician, who immediately referred her to the hospital with a diagnosis of lobar pneumonia.

The temperature was 103°F., the pulse 130, and the respirations 32. Physical examination showed a well-developed woman. The heart was not enlarged; there were no murmurs. The entire left lung was consolidated. The pulse was rapid. The uterus was enlarged to a size consistent with an eight months' pregnancy. The general physical condition was very poor.

Two days after admission, the patient started in

\*A series of selected case histories by members of the section will be published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the section. Letters should be addressed to Dr. Raymond S. Titus, Secretary, 330 Dartmouth Street, Boston.

labor and delivered herself spontaneously of a still born infant. She died the following day.

**Comment.** Pneumonia has always been recognized as a very serious complication of pregnancy. This death occurred before chemotherapy in pneumonia had been established, and although chemotherapy might have influenced this outcome, it is very doubtful whether the result would in any way have been changed after the patient was seen. This death can be attributed either to neglect or ignorance on the part of the patient. Why the patient had not consulted anyone is not clear from the record. Probably, her economic status had much to do with this, although prenatal clinics are available for those who cannot afford their own physician. It is essential that patients who are pregnant, particularly in the later months be warned about the seriousness of the common cold and that they be advised to have medical attendance immediately. In this way only may pneumonia sometimes be averted, and in this way only may chemotherapy be instituted soon enough to be of value.

As is very common in serious cases of pneumonia during pregnancy, this patient delivered herself spontaneously of a stillborn infant after a short labor. Recoveries do occur in some patients who seem desperately ill and whose uterus is spontaneously emptied, probably because the load on the heart is lessened and the lungs are given freer space for expansion. It is an obstetric axiom, however, that artificial induction should never be attempted.

## MISCELLANY

### PREVAILING INFECTION RATE OF TUBERCULOSIS

The mortality from tuberculosis has been quartered in forty years. This fact, however, reveals no accurate information regarding prevailing infection and morbidity rates. That they are less is too logical a deduction to be doubted but their decline relative to that in mortality has been a matter of conjecture. The following report on autopsy findings (Lande, K. E., and Wolff, G. Frequency of tuberculous lesions at autopsy *Am Rev Tuberc* 64:223-239, 1941) throws valuable light on this question especially since accurate studies extending over the past half century furnished the needed controls for comparison.

In 1900, Naegeli published a careful report of 508 autopsies. Of the adults over eighteen years of age 93 per cent showed healed inactive or active tuberculous lesions in the lungs. Only 17 per cent of those under eighteen yielded positive findings. Other investigators substantiated these findings, and in the early years of this century the belief was prevalent that all adults had at some time suffered an invasion by the tubercle bacillus.

Opie as late as 1917 found positive evidence of infection in all of 50 autopsies on adults and in nearly 24 per cent of a group of 93 children, the latter showing a

far higher figure in the adolescent years. These findings led Opie to remark, "Almost all human beings are spontaneously vaccinated with tuberculosis before they reach adult life."

In 1922, Watson reported positive findings in 82 per cent of his autopsies, and in 1925 Lambert and de Castro Filho reported a rate of 72.8 per cent in a large series from Brazil. As late as 1927, Todd still found evidence of tuberculous infection in 69 per cent of autopsies done in Edinburgh on patients who had died of some cause other than tuberculosis. Such evidence indicates rather clearly that the decline in infection rate has not kept pace with the mortality from this disease.

The present study was carried on at the Washington County Hospital in Hagerstown from September, 1938, to August, 1940, all autopsies being performed by the same pathologist. There were 176 autopsies during this period, which represented 45 per cent of the deaths that occurred. Eleven of these were rejected because they were not complete post mortem examinations, leaving 165, which are included in this report. Cases of active tuberculosis are not admitted to the hospital. The population of Washington County is semirural and most of the patients were long residents, from all classes of society and of the white race (there were only 4 Negro adults in the group).

Thirty-two of the 165 necropsies were done on children, and 133 on adults. For the whole group, positive findings were recorded in 65, or 39.4 per cent, which is just half of Naegeli's findings, 79.9 per cent, when he included all ages.

Considering only the adult group of 133 cases, the positive evidence of infection yielded 47.4 per cent again strikingly near half the number of adults found to be infected by the earlier researches of Naegeli, Burkhardt, Opie and others. In this series, there were 5 cases in which infection was suspected but could not be proved pathologically. If these are included, the percentage stands at approximately 50.

This finding of almost 50 per cent of positive tuberculosis among an unselected group of semirural population indicates that the frequency of tuberculosis is still sufficient to be alarming. If one assumes this experience as typical of the country as a whole, which seems reasonable, one must still face the fact that at least half of all adults have suffered invasions by the tubercle bacillus active enough to leave discoverable scars. This is disconcerting in face of the far greater fall in the death rate from the disease.

At the same time, there is some compensation in the discovery revealed by this study that only half as many people who have suffered tuberculous infection actually die of the disease as died forty years ago. The infection rate has been reduced to 50 per cent, and the mortality to 25 per cent of that in 1900. A number of factors have probably contributed to this gratifying preponderance in the decline of the death rate. Better sanatorium care and the management of cases have undoubtedly made a large contribution. The fact that lessening of the infection rate has apparently shown acceleration in the past fifteen or twenty years brings comfort to those engaged in both the preventive and the therapeutic aspects of tuberculosis control. A 50 per cent reduction in the reservoir of spreaders must certainly mean that fewer contact cases are today submitted to massive and repeated doses of infected material. The contribution of compression therapy and surgery to this result can but be inferred. Those who advocate freer use of these measures certainly would

seem to have little for which to apologize in the evidence presented by this study.

However, other factors in the picture, perhaps, deserve first mention. Isolation is the time-honored scheme for the control of epidemic, infectious disease. It is a significant coincidence that during the period when tuberculosis mortality was reduced to one quarter its 1900 level and the infection rate cut by 50 per cent, the sanatorium beds in this country increased from about 6000 to 100,000. It would be idle not to recognize this prophylactic procedure as an outstanding influence in lessening opportunity for infection among the general public.

The result of this procedure would have been far more striking had it been possible to arouse the medical profession to its responsibility in finding the early case and effecting its immediate isolation. Unfortunately, this is one of the weaker links in the control program. From three quarters to four fifths of all patients admitted to sanatoriums are still found to be in the advanced stages of the disease, already probable spreaders of the infection to others. More professional education, both undergraduate and postgraduate, is still needed to impress on physicians how truly further progress in tuberculosis control rests in their hands.

Popular health education and school hygiene have also played their parts in reducing opportunities for infection. Beginning with teaching the infectivity of sputum, the transference of disease through common utensils, uncleanness in restaurants and the menace of infected food handlers, instruction has proceeded to the point where even an open case is of relatively little danger to the patient's fellows if both he and they exercise the prophylactic measures now recognized as largely effective.

Finally, better housing, elimination of industrial hazards, more applied knowledge of the laws of nutrition and a growing consciousness of the significance of personal and community hygiene have played their part in reducing the transmission of tuberculous infection from case to contacts.

A highly significant factor in this study is the observation that reduction of infection as shown at autopsy has been at least as rapid among infants and children as among adults. These younger members of society can make no personal contribution to their own protection. They must rely on that of others—nurses, teachers, parents and relatives. Cutting their infection rate in two, as well as that of their elders, is clear proof that a better-informed public is making an increasingly effective fight against spread of this disease.

Frost, in discussing the eradication of tuberculosis, wrote as follows:

Tuberculosis also differs from the other directly transmitted respiratory tract infections in that its mortality has declined consistently for the last fifty years or more and continues to decline in every part of this country for which adequate statistics are available. It is not directly established by comparable statistical evidence that there has been a proportionate decrease in the prevalence of infective cases of the disease, taking into consideration not only the number of cases but duration of the open stage. However, there appears to be no good reason to doubt that the prevalence of open lesions effective in spreading the tubercle bacillus has diminished progressively, and continues to diminish in each considerable period of time.

However, it must not be overlooked that, according to present autopsy records, the reservoir of adults infected with tuberculosis at one time or another in their lives

still amounts to half the population. Therefore, tuberculosis can still flare up again whenever external conditions turn to the worse for the bulk of the people. Without such a reverse, there exists the hope that further effort in the campaign against tuberculosis will some day lead to a complete eradication of the white plague.—Reprinted from *Tuberculosis Abstracts*, November, 1941.

## NOTES

Twenty-three appointments to the teaching and research staff at the Harvard Medical School, effective during the present academic year, were recently announced as follows: assistants in medicine, Theodore B. Bayles, of Jamaica Plain, M.D. Harvard '36, L. Tillman McDaniel of Denison, Texas, M.D. Harvard '36, and Thomas A. Warthin, of Boston, M.D. Harvard '34; research fellow in medicine, Charles C. Bailey, of Boston, M.D. University of Virginia '37, Ephraim P. Engleman, of Cambridge, M.D. Columbia '37, Cutting B. Favour, of Washington D. C., M.D. Johns Hopkins '40, Abraham S. Freedberg of Newton, M.D. Rush Medical College '34, Harry I. Klinefelter, Jr., of Baltimore, M.D. Johns Hopkins '31, Julian E. Levi, of Boston, M.D. Johns Hopkins '38, Philip S. Owen, of Chester, Connecticut, M.D. Yale '37, and James V. Warren, of Columbus, Ohio, M.D. Harvard '35; research fellows in surgery, Rutledge W. Howard, of Jersey City, New Jersey, M.D. '37, and John E. Adam of Brookline, M.D. Harvard '39; research fellows in physiology, Douglas D. Bond, of Cambridge, M.D. University of Pennsylvania '38, Robert Galambos, of Cambridge, Ph.D. Harvard '41, and Manoel da Fronta-Moreira, of Rio de Janeiro, Brazil, M.D. National School of Medicine, Brazil, '40; assistants in ophthalmology, Franklin I. Burger, of Wellesley Hills, M.D. University of Michigan '36, and Thomas J. Cavanaugh, of West Roxbury, M.D.C.M. McGill '35; research fellows in pharmacology, Enrique M. de Espanes, of Cordoba, Argentina, M.D. University of Cordoba, Argentina, '28; teaching fellow in anatomy, Gabriel W. Lasker, of Brookline, A.M. Harvard '40; assistant in pediatrics, Winthrop I. Franke, of Jamaica Plain, M.D. Harvard '38; research fellow in biological chemistry, Thomas R. McLin, of Peoria, Illinois, M.D. Western Reserve '39; research fellow in legal medicine, Herbert S. Breyfogle, of Brookline, M.D. University of Chicago '37. In addition, Norman Weissman, of Boston, Ph.D. Columbia '44, was appointed a research fellow in dental medicine.

Dr. Frederic A. Gibbs, of Boston, was recently given one of the two annual Mead Johnson Awards by the American Academy of Pediatrics for his contributions to present-day knowledge of epilepsy.

Twenty-one Charles Hayden Memorial Scholarships were recently awarded to members of the first-year class at Tufts College Medical School. These scholarships are made possible through a gift of \$20,000 by the Charles Hayden Foundation, and they are awarded on the basis of financial need to young men who intend to enter the general practice of medicine. The recipients were as follows: Ward A. Albrow, Winchester; Frank A. Avola, Boston; George R. Bancroft, Jr., Winchester; Louis Burk, Chelsea; Joseph L. Cafarella, Malden; Robert C. Cornell, Mountain Lakes, New Jersey; Brendan F. Crotty, Jamaica Plain; Albert A. Delery, Somerville; Gordon N. French, Newton Center; Leon Herman, Brighton; Francis I. McCarthy, Chelsea; David E. McGaw, Winthrop; George B. McManama, Waltham; Stanley J. Mikalonis, South Boston; Edward S. Murphy, Jr., Belmont; Morris Sup

witz, Chelsea, John DeV Sweeney, Waltham, George J Tsolas, Watertown, George L Tully, Jr., West Newton, Lansing P Wagner, Cambridge, and William J White, Jamaica Plain

## CORRESPONDENCE

### INTERN SUPPLY AND DEMAND\*

*To the Editor* The editorial in the October 2 issue of the *Journal* concerning 'Intern Supply and Demand' contains assumptions both expressed and implied which we believe warrant discussion.

It is stated, 'Even if medical schools could increase their output and thus satisfy the demands for intern service . . . this merely means that a serious oversupply of practicing physicians would eventually occur, since the very increases in the utilization of hospitals that brought about the present disproportions have already diminished the practice of domiciliary medicine.' Though we may be mistaken, it appears that this statement points out that the field of private practice is growing smaller and, therefore, that the graduate output should be at a relatively fixed number, which in fact has been maintained for the past ten years. Yet it also recognizes that hospitals have been meeting a larger and larger medical need, both absolutely and relatively, in the community. It is evident, and the editorial expressly agrees, that the policy of a fixed supply of medical graduates must mean, in general, inadequate medical care where at present the greatest need exists. What should be done about this problem? To discuss it by deploring unfair competition among hospitals for interns and by warning the unwary intern against financial lures of inferior hospitals hardly seems adequate.

Whose needs should decide, in all fairness, the yearly number of medical graduates: the demands of organized medicine for a safeguarded private practice or the actual changing medical needs of the entire community? The editorial appears to imply that the yearly supply of medical graduates must be determined by the opportunities for the private practice of medicine. Yet one must agree that this criterion is hardly satisfactory if it prevents adequate care of the sick. In fact, an attempt to safeguard private practice at the expense of adequate care may well result in a dissatisfaction that will shorten the road to governmental medicine.

We should squarely face the problem of the community's need, which is, more physicians in hospitals. Is it not conceivable that if the number of physicians in hospitals bore a more reasonable relation to the increasing demands of the community on the hospitals, the present number of physicians would be more nearly adequate to the demand made on medicine? The problem, therefore, is not how to limit the number of medical students, but how to induce physicians to stay in the hospitals beyond the ordinary internship period.

The answer must be looked for in the reasons why interns leave the hospital. The intern's life as a rule consists of overwork, poor food and dependence or poverty. The present shortage of interns means increasing routine laboratory work and therefore steadily deteriorating educational opportunity in the internship. For a proper medical education, a longer period of hospital work is now necessary. This prolongs the individual's dependence. The long training period is extremely expensive, and as Dr Alan Gregg, of the Rockefeller Foundation, has recently pointed out, this means that medical graduates are being drawn from an increasingly restricted

financial group of society. This is hardly an intelligent or a democratic procedure, and Dr Gregg has suggested the subsidization of medical training as a remedy. Furthermore, recent advances in medicine have shown that, in every field, a man must have the fundamental satisfactions of life. This is the more true for physicians, who have to deal with tremendous numbers of patients who have failed in attaining some of these satisfactions. The blind cannot lead the blind! It follows that the medical graduate is in urgent basic need of a home, wife, children and financial independence. Is it any wonder, then, that medical men now yield unquestionably to the financial and other rewards of private practice?

It is obvious, therefore, that to induce physicians to stay in the hospitals, where they have to be to meet the needs of the community, the present setup will have to be altered fundamentally to permit them to lead normal lives as soon after graduation as possible. The Oslerian tradition of monasticism in medicine is incompatible with the demands of the modern physician. Nor does the easy statement of the older clinician, 'It wasn't like that when I was an intern,' get us very far, he has forgotten that he used to travel by horse and buggy, which he was delighted to see disappear.

We have spoken with many interns and resident physicians about the matters discussed in this letter. They agree that the points raised are well worth discussion from the point of view of the medical needs of the community, of enlightened medical practice, of the intern and of the practitioner.

### A GROUP OF RESIDENT PHYSICIANS

• • •

In the editorial space was necessarily limited, and the *Journal* is very glad to print further discussion. The names of the six residents who signed the letter have been omitted, at their request.

In considering the problem, one should bear the three following thoughts in mind: the fixed number of medical graduates represents the greatest possible output of American medical schools unless their present facilities are enlarged or their present educational standards are lowered, or both—whether it is the optimum number and why are other matters it is also a fact that the community must absorb and support the yearly supply of medical graduates—whether it does so through the channels of hospital, domiciliary, public or private care is a secondary matter, and will eventually be determined by the laws of supply and demand and the disproportions that are now apparent between the supply of and the demand for interns need correction, which was the reason that the subject was brought up for discussion.

The most immediate corrective measure would appear to be a lengthening of the years devoted to hospital practice, thus shortening those subsequently devoted to extramural activities, with whatever financial or other adjustments are available or obtainable therefor. Other, and perhaps more effective, corrections are no doubt possible. These must naturally be made in the interest of the recipients of medical care rather than in that of any group of its dispensers. Ep

### Erratum

In a letter by Dr George Saslow published in the November 6 issue of the *Journal*, the word 'no' was inadvertently omitted from the first sentence in the second paragraph. The sentence should read as follows: 'It might be thought that no special attention need be given

these points in the northern part of the United States, but this is apparently not so."

## BOOK REVIEWS

*Textbook of Pediatrics.* By J. P. Crozer Griffith, M.D., Ph.D.; and A. Graeme Mitchell, M.D. Third edition, revised and reset. 8°, cloth, 991 pp., with 220 illustrations and 66 tables. Philadelphia: W. B. Saunders Company, 1941. \$10.00.

In this, as in previous editions, the wide range of pediatric interest is covered with remarkable thoroughness when one considers the limitation of space imposed by a single volume. The new edition has been entirely rewritten, and the first portion, which deals with growth and development, has been materially enlarged. This is the field in pediatrics that the general practitioner who graduated several years ago will find particularly useful.

It is difficult not to deal in superlatives in considering this book, which can be unqualifiedly recommended both to students and to practitioners of medicine.

It is a tragic circumstance that since the book was written both the authors have died—Dr. Griffith on July 21 and Dr. Mitchell on June 1, 1941. This third and final edition by these two eminent pediatricians is therefore especially significant.

*Hutchison's Food and the Principles of Dietetics.* Revised by V. H. Mottram, M.A. (Cant.), and George Graham, M.D. (Cant.), F.R.C.P. (Lond.). Ninth edition. 8°, cloth, 648 pp., with 30 illustrations. Baltimore: Williams and Wilkins Company, 1940. \$6.75.

The ninth edition of this well-known\* book is a welcome addition to medical literature. The original volume was first published in 1900, so that in forty years not only have nine editions been issued, but each edition has been many times reprinted. It has become a standard book on the subject, in both Great Britain and this country, and is a lasting monument to Sir Robert Hutchison, who originally compiled the material and gave the medical profession one of the outstanding books on the scientific aspects of nutrition and the treatment of diseases.

There have been changes in the knowledge of nutrition, particularly in relation to vitamins, since the eighth edition was published. In addition, the world has become conscious of the value of foods, not only in the treatment of disease, but in the general welfare of populations, particularly in relation to war conditions. Wartime has always proved an incentive to the study of dietetics, and the present era is no exception to this rule. The new edition of this book considers the more recent advances in the nutritional field.

*Hemorrhagic Diseases: Photo-electric study of blood coagulability.* By Kaare K. Nygaard, M.D. 8°, cloth, 320 pp., with 59 illustrations. St. Louis: The C. V. Mosby Company, 1941. \$5.50.

This book represents a serious attempt to study the mechanisms of blood clotting by the use of a photo-electric technic. A "coagelgram" is obtained by photo-electric scanning of the clotting of recalcified plasma. To the reviewer, the detailed descriptions of the various steps in the clotting process, as mechanically observed, are of less interest than the excellent reviews of the literature and the discussions of the nature of the coagulation problem. It cannot be denied, however, that the introduction of exact standardized methods in any problem is desirable. In the discussion of thrombocytopenic purpura,

perhaps too much attention is devoted to the minor changes in plasma clotting time and to the highly hypothetical "thrombocytolytic activity of the entire reticulo-endothelial system." A good discussion of hypofibrinogenemia, both in adults and in the newborn, is presented.

Whether or not any unusual light has been shed on the problems of coagulation in this monographic presentation of the author's numerous experiments, there can be no question that Nygaard has performed a distinct service by his painstaking and original investigations, which were for the most part performed while he was a fellow in surgery at the Mayo Clinic.

## NOTICES

### GREATER BOSTON MEDICAL SOCIETY

A meeting of the Greater Boston Medical Society will be held at the Beth Israel Hospital on Tuesday, December 2, at 8:15 p.m.

#### PROGRAM

The Practice of Medicine in Historical Perspective. Dr. Henry E. Sigerist, professor of the history of medicine and director of the Institute of the History of Medicine, Johns Hopkins University School of Medicine. Discussion will follow by Drs. Hugh Cabot, Reginald Fitz and James C. McCann.

### BOSTON DISPENSARY

There will be a clinical staff meeting of the Boston Dispensary in the Pratt Hospital Auditorium on Wednesday, December 10, at 12:30 p.m. Dr. Warfield T. Longcope, physician-in-chief, Johns Hopkins Hospital, Baltimore, will speak on "Virus Pneumonia," and the discussion will be led by Dr. Maxwell Finland. Luncheon will be served at 12 m. All interested members of the profession are cordially invited to attend.

### BOSTON HEALTH LEAGUE

A special meeting of the Boston Health League will be held at Perkins Hall, 264 Boylston Street, Boston, on Friday, December 5, at 12:30 p.m. Dr. Harold C. Stuart will speak on "Nutrition in Unoccupied France."

### JOSEPH H. PRATT DIAGNOSTIC HOSPITAL

Bennet Street, Boston  
Lecture Hall, 9-10 a.m.

#### MEDICAL CONFERENCE PROGRAM, DECEMBER

Wednesday, December 3—The Pathologic Physiology of Hypertension: Some recent developments. Dr. R. W. Wilkins.  
Friday, December 5—Errors in Cardiovascular Diagnosis. Dr. Paul D. White.  
Monday, December 8—Clinicopathological conference. Dr. Warfield T. Longcope and Dr. H. E. MacMahon.  
Tuesday, December 9—Medical clinic. Dr. Warfield T. Longcope.  
Wednesday, December 10—Atypical pneumonias. Dr. Lowrey Davenport.  
Thursday, December 11—Epidemiology of Hemolytic Streptococcal Infection. Dr. Chester S. Keefer.  
Friday, December 12—Medical clinic. Dr. Warfield T. Longcope.  
Saturday, December 13—Treatment of Pneumococcal Pneumonia with Sulfadiazine and Serum (motion picture).

## WHY FIRST AID?\*

A WILLIAM REGGIO, M.D.†

BOSTON

THE medical literature is filled with articles about the treatment of injuries and the shock accompanying them. The public expects the physician to accomplish miracles in saving the life of some smashed up victim or in restoring him to normal again, no matter what the accident or in what condition the patient has been brought to the hospital.

Physicians not infrequently criticize the layman for the way in which such injured persons are brought to them, but, it is pertinent to raise the question, What is the medical profession as a whole doing to improve the first-aid care of the victims of accidents?

The laymen are doing considerably more in that direction than physicians, who as a group, I am afraid, are considerably to blame for this state of affairs. Their greater interest in the treatment of injuries after the victim has been taken to the hospital and their failure to emphasize the care to be given such a person from the very instant after the accident occurs are major factors.

To be sure, more recently, greater attention is being paid to the immediate or first care that these victims require, but most of the emphasis is still being placed on the care that comes after the ambulance has "rushed the victim to the hospital" (with or without police escort).

Although what is done for such patients once they are in the hospital is of the utmost value and deserves much space in the literature, one should not forget that it is to the physician's advantage, as well as to that of the patient, to have these cases brought to the hospital with as little additional shock and damage as possible. Great care should be taken immediately after an accident, and that is when first aid finds its place.

First aid is the immediate and temporary care

given by trained persons in case of accident or sudden illness before the physician takes charge." This definition is taken from a manual‡ recently published by the American Red Cross.

In 1940, there were 8,800,000 accidental injuries in the United States, 93,000 of which resulted in the death of the victim. Of these deaths, 32,600 were due to automobile accidents, and 25,800 to falls. This means that out of 24,000 accidents that occur each day in the United States, 255 of the victims die. As of April, 1941, there were about 186,000 physicians in this country. With 170,000 accidents occurring each week, it would mean that every physician—if all accidents were immediately seen by a physician as the first person to arrive on the scene—would care for 48 accidents a year. Of course, this is quite useless figuring, except so far as it brings out the fact that the great majority of accident victims must receive their first aid care from a layman who "holds the fort" until the services of a physician can be obtained.

The first-aid care given by a layman often makes the difference between life and death for the victim, and it is reasonable to suppose that a physician will be very grateful that the case has been adequately cared for by some layman, who has thus given the physician a fighting chance to get his patient through alive.

The training of laymen in first aid was begun by the American Red Cross in 1910, when the first class was taught and the first certificates for the successful completion of the course were issued. From 1910 to 1935, the first million certificates were issued, from 1935 to 1939, the second million, and from 1939 to 1941, the third million; and now the number of people asking for and receiving instruction in first aid is nearly double that of a year ago. The fourth million certificates are now

\*Read by title at the annual meeting of the New England Surgical Society, Harvard New Hampshire September 5, 1941.

†Instructor in surgery, Harvard Medical School, assistant visiting surgeon, Massachusetts General Hospital, chairman, First Aid, Boston Metropolitan Chapter, American Red Cross.

‡First Aid Manual for Civil Defense Units. 16 pp. Washington: American Red Cross, 1941.

well on their way, 410,966 having been issued during the last twelve months. For the same period, that is, from July 1, 1940, to June 30, 1941, 10,406 instructor's certificates were issued; several thousand additional instructors were trained during this period, but all the certificates have not as yet been issued. Also, as of June 30, there were available for use as active first-aid instructors 30,871 men and women. Most of these are laymen trained and retrained by the Red Cross, but some are physicians appointed by application only.

The American Red Cross offers four courses in first aid. The junior course gives boys and girls from twelve to seventeen years of age instruction in the principles and application of first aid. This course requires a minimum of fifteen hours. Then comes the standard course, which calls for a minimum of twenty hours of teaching and usually requires nearer twenty-five hours for satisfactory completion. The standard course may then be followed by an advanced course, which requires a minimum of ten more hours. Finally, there is the course for instructors in first aid, which requires an additional fifteen hours of teaching after completion of the standard and advanced courses. Both written and practical examinations are given at the end of all these courses and must be successfully passed if a qualifying certificate is to be obtained. Instructors are authorized to conduct the junior, standard and advanced courses, but not the course for instructors, which is given only by specially qualified and authorized instructors approved by headquarters of the American Red Cross in Washington.

There has been and there still is a certain amount of unfavorable criticism and objection on the part of some physicians to the rendering of first aid by laymen. Although poorly administered first aid may be worse than none, proper and adequate first aid, correctly given by a trained layman, may often be the deciding factor between survival and death of the victim of an accident. Of course, there are good first aiders and poor ones, as there are good physicians and poor ones.

Just why this sporadic opposition to the training of laymen in first aid is still maintained by a certain number of physicians is in one way difficult to understand, although in another way the answer is simple. In plain language and without any apologies for making such a statement, the underlying reason for this attitude is ignorance of what first aid really is. They do not know how or what the layman is taught. They criticize the methods taught because these methods do not happen to coincide with what they themselves would do. They have not taken the trouble

to find out anything about first aid and not infrequently assume this superior attitude to cover up their own ignorance.

A well-trained first aider can teach a doctor many a valuable trick, provided the doctor is not too superior to be willing to learn from a layman. How many doctors out of the 186,000 in this country are familiar with what is taught in a course in first aid, or are really qualified, off-hand, to teach such a course to laymen? It is doubtful if 4 per cent, or about 7500, could do so on the instant, without first learning more about the subject.

Quite a number of physicians who are interested and are willing to be instructors take the standard, advanced or instructor's course to familiarize themselves with the methods they are to teach. It is unfortunate that any doctor of medicine who is a graduate of a Class A medical school, and who is without Red Cross training, may be appointed an instructor in first aid to teach the junior, standard and advanced courses merely on his request for a certificate from the Red Cross. On the other hand, graduates of unapproved medical schools or members of the cults would have first to take the standard, advanced and instructor's courses and pass them successfully, before they could receive a certificate authorizing them to teach.

First aid as rendered by a physician not only may be but frequently is a very sad substitute for what could be done by a trained layman under similar circumstances. Naturally, the layman steps aside when a physician arrives to assume responsibility for the care of a victim, but often the injured person would have received better first aid had the trained layman been allowed to render it instead of the doctor. This is particularly applicable to fractures at the scene of an accident.

Trained laymen know how to use a Keller-Blake leg splint, or a notched board or rake as substitutes, and how to apply fixed traction for safer transportation of the victim. Many physicians do not even know what a Keller-Blake splint is, much less how to apply one, and even less how to improvise or use substitutes.

Another difficulty too frequently occurs during a course in first aid. The class or the instructor invites a physician to attend an exercise and give advice or answer questions. The result is that the physician often condemns traction splinting or some other method of rendering first aid because he, himself, is opposed to such a procedure (or ignorant concerning it), or is personally convinced that a trained layman is not qualified to employ such a method. Of course, it is discourag-

ing to the class and the instructor (who are doing their utmost to be efficient) to be casually informed, with the voice of pseudoauthority, that they are all wrong because that particular physician happens to disagree with or be ignorant concerning methods approved by the American Red Cross, the American College of Surgeons, the Bureau of Mines, the American Association of Railroad Surgeons, the National Safety Council, the National Ski Patrol and numerous similar organizations, to say nothing of physicians outstanding in the field of traumatic surgery throughout the country. The underlying cause of this trouble lies in the fact that medical schools do not teach first aid to their students, and that their graduates consequently know nothing about the subject. It is not the fault of the students but of their instructors.

In a checkup of the medical schools of the country conducted during 1940 by a special committee of the American College of Surgeons, it was found that not a dozen medical schools taught anything about first aid, except for the application of emergency splinting as part of fracture instruction. In half these schools, attending a course in first aid is optional for the students. First aid should be a required course in the first or second year in every medical school.

I take the liberty of quoting two sentences from a personal communication on this matter, since they so aptly bring out the point in question.

First, it serves to give some practical medical work and useful information to the students in their first and second years that they are able to assimilate at least as well as Boy Scouts and those who attend Mothers Meetings. In the second place, since many of these boys take positions as camp counselors or camp physicians in their summer vacations, a first aid course is of more value to them under these circumstances than the other courses of their first two years are biochemistry, pathology, bacteriology and the *Lives of the Saints* are all of about equal value for a camp counselor and camp physician.

Most medical students and even the younger hospital interns could be put to shame in the rendering of first aid by almost any First Class Boy or Girl Scout or trained layman.

Physicians should consider honestly whether they are able — offhand — to teach a layman the following procedures of first aid care according to the standards of the American Red Cross: the prone pressure method of artificial respiration; detection of the signs and symptoms and first aid care of snake bite, the application of a Keller-Blake and a Murray-Jones splint; traction splinting with some substitute when these splints are not avail-

able; bandaging a hand, ankle or foot with the triangular bandage, open or folded.

It is no simple matter to render adequate first aid on the open road when materials have to be improvised and the complete equipment of a hospital accident room is many miles away. I have seen injured people brought to the hospital who had received first-aid care from a physician, and it has struck me that I should much prefer to have been handled by a well trained layman under similar circumstances.

This training of laymen should be encouraged, and the physician is the one who can give this encouragement, because in his contact with his patients and with community interests he can, if he will take the trouble to inform himself beforehand concerning it, arouse interest.

All police and fire departments should have their men trained in first aid. This is being slowly accomplished against considerable opposition. One must realize that people taking the course do so voluntarily and usually during their free time, and that there is no financial reward connected with it. It is just one of those unselfish things that may bear fruit if the emergency arises.

The fact has frequently been commented on that when a person knows how to render first aid, it makes him more careful to avoid accidents because, knowing the result of an accident, he is likelier to think twice before running such a risk.

When motoring along the highways, one sees quite a number of signs — usually near gasoline stations — indicating the location of a highway emergency first-aid station under the auspices of the American Red Cross. This means that the men connected with that station have taken the standard course and are qualified and equipped to render first aid when necessary. Many large industrial concerns, gas, electric and telephone companies, department stores — in fact, almost any manufacturing or public service organization in the country — have a department that concerns itself with the training of employees in first aid. The first step is usually to have a certain number of employees take and pass the standard, advanced and instructor's courses, and then, in turn, give the standard course to other employees.

Another thing that, by the thoughtful co-operation of the press, could be changed is the spectacular reporting of "rushing" injured people to hospitals. The newspapers seem to love the dramatic appeal of this word and fail to realize that, by this excess of speed, not only are other people and vehicles endangered, but the unfortunate victim has shock increased by the joggling

and tossing about that he gets during his ride. If the ride were less hasty and at a moderate, safe speed,—and, if possible, in an ambulance,—the victim would, not infrequently, arrive at the hospital in better shape than when he started. However, the public loves the dramatic whether it costs a life or not.

In the present national emergency, defense councils or committees on public safety have been set up in all the states of the Union. One of their activities deals with the care of the injured as a result of property damage of one sort or another. In connection with this, each community is providing a large number of air-raid wardens, who are to be trained in their particular tasks of coping with property damage and attempting to give the bare essentials of first aid to injured people as well.

In Massachusetts, as a result of the insistent demand of the State Committee on Public Safety,

the American Red Cross has added a short course in first aid taught only to persons enrolled as air-raid wardens; this short course in no way supplants the standard course. In fact, all persons taking these ten hours of instruction are urged to follow it up, if possible within six months, with the standard course. The distribution of *First Aid Manual for Civil Defense Units*, printed by the American Red Cross, is confined in Massachusetts to officially recognized defense groups.

Physicians have a firm conviction that "life is more valuable than property," and strive in every way to preserve that life. In the event of an accident, the care or treatment begins at once or as soon as possible after the occurrence. With some 9,000,000 accidents taking place each year, it seems reasonable that physicians should act according to what they say about the value of life—in other words, acknowledge that first aid is worth while. Why first aid? Why NOT?

374 Marlboro Street

## THE CARDIOVASCULAR ASPECTS OF AVIATION MEDICINE\*

JOHN R. POPPEN, M.D.†

WASHINGTON, D. C.

THE introduction of aircraft into warfare during World War I gave promise that if another cataclysm should eventuate it would have an even more extended application. The present conflict has fulfilled that promise to a greater extent than anyone had anticipated. The prediction that success in war would be largely dependent on aerial supremacy is being vindicated daily. The position of aircraft in the world today is exemplified in the extended interest in aviation medicine displayed by the medical profession. This interest springs not only from curiosity but from a patriotic desire to render to the nation the wholehearted and complete service that is expected of American physicians. It is in times of stress like the present that we of the regular services have to depend on that assistance, and our humble appreciation can be understood.

The problem of the flight surgeon is included in the selection of flying personnel and keeping them in the air.

Aviation medicine is peculiarly subclinical in its field of interest and application. In this respect, it is the acme of preventive medicine. We are most exacting in the choice of our clientele, and

the art of our practice is designed to preserve a degree of fitness for a peculiarly exacting mode of life, which is different from and of higher degree than that necessary for any other field of endeavor. For these reasons, it is tremendously necessary for us to have available and make use of any and all armamentaria that will make our selections sound and our practice healthy.

The selection of flying personnel requires, first of all, freedom from organic disease. This is true of the entire economy but particularly so of the cardiovascular system because of the unusual strain to which it is subjected in flying. The heart is insulted by flying. In recent years, we have become more and more impressed with the importance in the development of cardiac disease of what may be called the pace of life. We may differ in our opinions of the relative significance of this factor in the development of, specifically, coronary thrombosis, as compared to infectious disease, heredity, diathesis or other causes, but the fact remains that the incidence of demonstrated coronary disease has risen *pari passu* with an increase in the tempo of existence in the present highly mechanized and speedy era. Flying is outstandingly of this order. It depends on speed and its concurrent, rapid change of environmental aspect and on the necessity of swift and accurate

\*The Henry Jackson Lecture, delivered before the New England Heart Association, May 2, 1941.

†Commander, Medical Corps, United States Navy; head of Medical Research Section, Bureau of Aeronautics, Navy Department, Washington, D. C.

adjustment to these changes. Whether or not this degree of stress is controlling in the development of organic cardiac disease, it would be folly to permit a person deliberately to subject himself to it if he already has evidence of actual or potential organic disease.

Flying requires adjustment to a new and unusual set of circumstances in its three-dimensional fields. With rapid changes in altitude come the problems of anoxia and high accelerations. The burden on the heart of maintaining adequate circulation in the presence of high degrees of anoxemia is well known. The profound changes in blood distribution incident to the centrifugal forces encountered in certain maneuvers place a peculiar burden on the circulation, in which the heart has its share. The responsibility of repeatedly and suddenly requiring an effort to preserve the circulation against profound reduction and inadequate filling of the right heart is peculiar to flying. These are unhuman circumstances, and for that reason especially trying. They are not reasonable tasks to present to a heart unless it is free from actual or incipient organic inefficiency.

For the determination of actual or incipient organic heart disease, we must depend on the diagnostic methods commonly used in physical examination. Careful history, keen inspection, accurate percussion and clear auscultation continue to be the most reliable diagnostic tools. Adjunctive aids in the form of electrocardiograms and x-ray plates must remain supplementary for those cases in which commoner methods of examination do not suffice to make the diagnosis clear. Under present circumstances, when it is necessary to examine and certify large numbers of flying applicants, it is administratively impractical to include in the records the comprehensive and complete data desirable in a clinical case history or for the preparation of a scientific treatise.

This does not mean that these diagnostic aids should be neglected. The electrocardiograph should have a well-established position in aviation medicine. It would be tremendously desirable to have on record a tracing of every aviator when he begins training. For purely diagnostic purposes and for the detection of arrhythmias, blocks and coronary disturbances, such data would be invaluable. For interpretation in terms of subsequent tracings, taken incident to routine periodic examination or when indicated by intercurrent findings, their value is manifest. It is generally agreed that these original tracings should be made and filed.

Again, taking routine periodic tracings, particularly in certain age groups, would be highly

desirable. For a complete record on which to be absolutely sure that the heart continues in high efficiency, such routine examination must be considered indispensable. But the desirability of this procedure must be weighed in the light of administrative capabilities.

To equip all points of original examination with apparatus would seriously tax the industry and would represent an outlay of federal funds that might be justly criticized in time of pressing need for rigid economy. To staff all recruiting stations with trained personnel to make the tracings would require either that civilian institutions be stripped or that intensive training be instituted. To assign to suitable stations enough physicians capable of accurately reading the tracings in the tempo required for defense would deplete the ranks of cardiologists needed by hospitals and educational institutions. How accurate electrocardiographic readings can be obtained on all incoming aviators with sufficient expedition to eliminate those showing sufficient evidence to debar them from flying, not to prevent those whose tracings are well within normal limits to begin training and not to impede a pressing training schedule is a serious question.

At the moment, the problem of fitting electrocardiography into selection of prospective aviators is more urgent than the routine examination of certain age groups. In time of peace, when schedules can be sufficiently flexible to arrange for the transfer of all pilots in certain age groups to central points for electrocardiographic study, the best that could reasonably be expected would be annual examination of pilots over forty years of age. In times of emergency, such as the present, routine stated examinations are virtually impossible. In answer to the argument that one pilot grounded would pay for the procedure, it can be pointed out that separation of a considerable group from points of strategic importance might jeopardize a campaign. The solution to this problem is not apparent. It appears certain that a well-organized and competent program, to effect this desideratum, may have to give way to expediency.

In the choice of selection methods on the personality or psychologic side, we are considerably handicapped by the absence of a good working definition of an efficient pilot. One difficulty in validating tests is the fact that we do not have a negative criterion group. This may be said about all phases of the examination. We do not know, for example, whether epileptoid trends make a poor pilot. It may be pertinent to ask the same question about cardiovascular findings. What degrees of variation from the normal mean electro-

cardiogram may be considered perfectly compatible with flying? Again, should electrocardiographic findings that are regarded as definitely contraindicating certain walks of life requiring strenuous exertion necessarily be considered a cause for rejection for flying?

In discussing the cardiovascular aspects of flying in its application to the maintenance of flying fitness, emphasis will be placed on two major considerations: the cardiovascular demands peculiar to flying, and tests for determining cardiovascular efficiency.

In considering the demands of flying at high altitudes, it is safe to conclude that the burden on the heart and blood vessels is no greater than that introduced by the necessity of compensating for anoxemia or oxygen debt incident to other causes. Some forms of athletic exertion are vastly more demanding than the anoxia of high-altitude flying. Indeed, flying is characterized by an absence of physical exertion commensurate with the situation. This has a specific significance in its biochemical aspects. Emotional stress or a misguided urge to get the most out of oxygen equipment may stimulate hyperventilation out of proportion to that required by the amount of carbon dioxide produced by comparative muscular inactivity. The resulting acarbica may have very serious consequences. But this is essentially a chemical problem and is not appropriate to this discussion. From the point of view of anoxia in high-altitude flying, per se, the cardiovascular demands are not excessive.

A chain of physiologic events incident to rapid changes in the direction of flight may be of interest. These alterations result from the introduction of centrifugal acceleration along the long axis of the pilot's body during certain aerial maneuvers. The attendant symptoms—commonly grouped under the term "blacking-out," and popularly ascribed to the pull-out following a dive at high speed—have been extensively described. The physiologic changes have not been so well described.

The physical force involved is the hydrostatic tendency of the blood to be thrown into the lower parts of the body at the expense of the upper parts. In virtually all aerial maneuvers, the direction of gravitational force is normal in that it applies along the vertical axis of the airplane, which means the long axis of the pilot's body. High accelerations along this axis develop most commonly in the pull-out from a dive and in turns of short radius, such as those seen in aerial combat. In the former, these forces may attain the magnitude of nine or ten times normal grav-

ity (9 or 10 g in gravity units). In the latter, they seldom exceed 5 or 6 g, but are usually of longer duration. Both the magnitude of the centrifugal force and the duration of its application are of critical significance. Thus, the greater strength during a pull-out may be of less consequence than the longer duration during a dogfight. For this reason, it is a mistake to consider the effect only in terms of its magnitude. Indeed, the necessity of guarding against the effects in short radius turns is greater than that in pull-outs following terminal velocity dives. This will be even more apparent when the lesser, subclinical symptoms resulting from the physiologic changes are considered.

In considering the changes in blood distribution, it is well to separate the synchronous changes in the arterial and venous columns. If one regards the arterial column from the cranium to the pelvis as fluid confined in a semielastic tube under a pressure of a couple of pounds per square inch subjected to a centrifugal force downward, it can easily be seen that there will result a tendency toward greater pressure and volume in the lower portion at the expense of the upper. The carotid pressure will drop. The venous column is under much less pressure, and the vessels are less elastic. The changes in the venous column are the same as those in the arterial, with this additional feature: if the gravitational force lasts long enough, the column of venous blood is driven below the level of the right heart. Inadequate filling and reduced output result. The carotid pressure drops, because of the force acting on the arterial column; a secondary and more profound drop, incident to reduced cardiac output, follows. For this reason, the venous changes are of greater importance and constitute a direction of approach in attempting a solution.

Given a profound drop in carotid pressure and a greatly increased jugular suction, one is faced with the question of what happens in the closed cranium. If the cerebrospinal fluid in the spinal column were available, one could expect that the sinuses would collapse with the increased arachnoid filling of cerebrospinal fluid. But the cerebrospinal fluid has the same tendency to leave the cranium because of subjection to the same centrifugal force. If arterial blood were available, one might expect a relative increase in the volume of blood in the arteries to compensate for venous collapse. When one remembers, however, that these changes extend over only a few seconds, it is safe to conclude that there can result no compensatory adjustment in relative volumes of the three fluids within the cranium. This leaves only

one vascular end result—a profound reduction of velocity of flow through the cranium. The symptomatology is easily explicable on the basis of the resultant local, transient cerebral anoxia. This explanation is more tenable than the theory of concussion, of sliding of the cerebrum over the tentorium, with impingement of the posterior cerebral arteries and ischemia of the occipital lobes, or of molecular changes in the neurones or any other theory advanced to explain the symptoms of high acceleration.

There is another feature of the symptomatology that supports the concept of cerebral anoxia and points to its most serious import. The experience of blacking out in pulling out from a steep dive is strikingly poignant. There can be no doubt that the pilot has been subjected to a force of tangible magnitude. It will immediately cause something in response—often something wrong. But the anoxia has all the attributes of that produced by any other method. It is identical to anoxia at high altitudes, with the sole exception that it is shorter lived. The most dangerous aspect is its insidiousness in degrees below those resulting in subjective symptoms. As a result of being subjected to high acceleration, a pilot may be the victim of decreased mental efficiency well below the threshold of awareness, but particularly dangerous because of this insidiousness.

The desirability of developing means for obviating the effects of high acceleration is manifest. It is regretted that time, inconclusive proof and, possibly, national advantage do not permit extended discussion of these means. Certain procedures have already proved to be partially effective, and there are scientific findings that lead to other possibilities. The answers will of course be found.

The cardiovascular problem of maintaining flying fitness is largely that of avoiding the development of what has been variously named but fairly uniformly defined as "neurocirculatory asthenia," "effort syndrome," "soldier's heart" and so forth. I prefer the term "staleness" because it avoids the implication that the condition is exclusively a circulatory disturbance, particularly in its etiology. The psychogenic aspects of its etiology are so strong that the early manifestations may be only changes in emotional and temperamental reaction, which often antecede circulatory changes by an appreciable and important interval.

The condition can be accurately diagnosed in the hospital, but when it has progressed to a degree that makes this possible, it is altogether too late for the flight surgeon. If the condition is to be avoided or relieved before it reaches the stage

of hospitalization, it must be disclosed in its earliest and most incipient stages. These patients practically never return to operational flying from hospitals. The task of discovering early evidences and instituting curative measures constitutes the major mission in the practice of aviation medicine.

The competent and experienced flight surgeon, in his capacity of "Dutch uncle" and father confessor,—who lives in daily and nightly contact with his pilots, becomes their confidant and mentor, and is alert to small but significant changes without ostentation,—exemplifies that side of medicine which must always constitute the immediate contact between physician and patient. The principal tools in his armamentarium are his observation, appreciation and compassion. Would that there were more of him today!

During a generation, we have become accustomed to a circulatory efficiency rating using the Schneider index. Six factors—reclining pulse rate, standing pulse rate, increase in pulse rate from reclining to standing, increase in pulse rate following standard exercise, time of return to standing rate, and change in the systolic blood pressure from reclining to standing—are scored on the basis that each is capable of a score of 3. The six are added, giving a total score or index.

The Schneider index has come in for considerable criticism of late, some of it fairly acrimonious. It is claimed that this test does not measure circulatory efficiency. It disregards diastolic and pulse pressures. It gives no indication of circulation time or output per beat. It makes no mention of respiratory indications of circulatory efficiency, such as vital capacity, breath holding and expiratory force. In other words, it is claimed to fall far short of determining what it is supposed to determine.

Before complete condemnation is heaped on the test, however, it may be worth while to consider the use made of it and some of its advantages. In the practice of aviation medicine, the index is applied both in the selection of students and in routine maintenance.

The circulatory efficiency rating is given careful consideration in the original examination. It is seldom, if ever, considered a cause for rejection, per se. If the rating continues low after all possibilities of organic or functional cardiovascular disease have been eliminated and after adequate food and rest have been provided, it must be regarded as an indication of inadequate or unsatisfactory emotional control. If organic disease is disclosed the disease is considered the cause for rejection. If emotional instability remains as the cause for a low rating and is confirmed by other

findings, the instability is the cause for rejection, and the test falls more properly into the neuropsychiatric examination. A low rating is of considerable value in the original examination.

In routine practice, the Schneider index is commonly taken. It is often performed and scored by trained, enlisted technicians. In these situations, it is considered purely as an index, a cue to further study. If it is low because of rapid pulse, fever or intercurrent infectious illness, the index directs attention to the illness. On the other hand, it may be low because of incipient fatigue or neurocirculatory asthenia. In any event, it is used only as an indication for further study. It is particularly significant in the light of a person's normal average as established during a long period of fitness.

The Schneider index may have many shortcomings as a test of neurocirculatory efficiency. We do not use it as such. It has many advantages. It can be administered by comparatively untrained assistants. Anyone who can count and read a watch and a blood-pressure dial can run the test. It requires a minimum of equipment, and can be completed in ten minutes. It is adaptable to service use, wherever that may take it. It gives very valuable information if properly interpreted.

Finally, it has become a tradition. It pervades the literature and drama of aviation medicine. It is of extreme interest to the pilots themselves. It is one thing to explain to a pilot that his cardiac efficiency has improved, as indicated by increased output per beat, or that his vasomotor control is waxing or waning. It is an entirely different matter to tell him that his index is 10, as compared

with his normal index of 14. To personnel trained in accurate mensuration and accustomed to judging on the basis of mathematical readings, a numerical score is tangible and comprehensible. The pilots are sometimes the severest critics of the index. It is completely invalidated when it proves to be high after a bad night. An explanation of the significance of relaxation and composure, coupled with the unstinted confidence of such discussion, serves to cement association, and the index, again, has served a very useful purpose.

Scientific research and study may furnish a much better criterion of circulatory efficiency, but unless it can compete in service adaptability, practicability and comprehensibility, it will encounter opposition in its acceptance.

\* \* \*

The motto of military aviation is, "Keep 'em flying." The service aviators of this country are a choice group of men. They are strong in character, mind and body. They are keen, clear thinkers. They are intelligently critical. They hold a key position in the defense of the nation. They must not be impeded. In all that we do in our mission of keeping them fit to hold that position, we must be scientific, but we must also be practical. Above all, we must not lose sight of the fact that our responsibility is less toward the aggrandizement of general or personal scientific concepts than to the care of the finest group of men in the world. In these days of turmoil and rapidly changing opinion, we must preserve a middle-of-the-road course as mapped by sound, proved facts.

## SUPPURATIVE PERICARDITIS\*

RALPH ADAMS, M.D.,† and HUGO POLDERMAN, M.D.‡

BOSTON

THE difficulty of diagnosis of suppurative pericarditis and the general agreement among thoracic surgeons about principles of therapy, although not about details, suggest the desirability of periodic restatement of accumulated knowledge of the disease. Although this report is based on consecutive experience with suppurative pericarditis at the Massachusetts General Hospital during the last ten years, and although the total experience is essential background, the advances of recent years require a reevaluation of concepts in relation to the disease and a revision of the therapeutic program in many ways.

The pessimism of the medical profession concerning acute pericarditis was expressed by Cabot<sup>1</sup> in 1926. "We can recognize this disease in only one fifth of the cases and can usually do nothing to cure it. Its clinical importance is therefore small." Winslow and Shipley,<sup>2</sup> in their excellent reviews in 1927 and 1935, however, presented a different picture, at least for purulent pericarditis: about 50 per cent of the cases treated with operation were cured.

A few outstanding facts may be presented at the beginning. The mortality of pericarditis is high because the disease is itself a complication of pre-existing and usually serious infection elsewhere in the body. The diagnosis is difficult and therefore delayed, but the possibility of a favorable outcome is enhanced by early treatment. The only effective therapy is surgical drainage. The recently introduced serologic and chemotherapeutic agents afford additional methods of therapeutic aid that are very promising. A number of articles emphasize the value of surgical treatment of the disease,<sup>4-6</sup> but it appears from the older as well as from the more recent publications that, even with adequate drainage, only half the patients can be saved. Death is often due to multiple lesions elsewhere in the body, as in staphylococcal and streptococcal infections, or to overwhelming infection and exhaustion, as in pneumococcal infection. Bigger<sup>6</sup> reported 9 operative cases, with recovery in 5. Bunch<sup>7</sup> obtained 2 cures in 4 cases. The numerous reports of single successful cases yield little information about the percentage of cures because single failures are seldom

reported. Most of the cases operated on and reported until now were treated before chemotherapy and immunotherapy were generally applied. It seems likely that these forms of treatment may be of great help in the management of purulent pericarditis.

Therapy is discussed in great detail in the following case, for the purpose of emphasizing the advantage of combining all modern therapeutic procedures.

## CASE REPORT

CASE 7 (M. G. H. 753933). A 5-year-old boy was admitted to the Massachusetts General Hospital on February 14, 1940, with a diagnosis of bronchopneumonia and pericarditis. Two months before entry he developed pain in both ears and fever. The middle ear spaces were drained eventually of staphylococcal pus with improvement, but a week later, signs of pneumonia appeared. The pulse was 140, and breathing was rapid and shallow. The ear drums were healed. The cardiac percussion area was greatly enlarged and a pleuropericardial friction rub was heard on the left side. The apex impulse could not be seen or felt and the heart sounds were of low intensity and muffled. There was a paradoxical pulse. The liver edge was palpable, and there was slight edema over the sacrum. The neck veins were distended. Dullness and absence of breath sounds in the left axilla were indicative of pleural fluid. On x-ray examination the heart shadow was enlarged and no pulsations were visualized by kymography. There was a left-sided encapsulated empyema. An electrocardiogram showed tachycardia and elevation of the ST intervals, suggestive of pericarditis.

The pericardial cavity was drained on February 19, without preoperative aspiration. Under local anesthesia, a curved incision was made along the left 7th intercostal cartilage, extending upward to the 5th. The 5th, 6th and 7th cartilages were resected. The pericardium was incised, and 250 cc of purulent fluid, which had displaced the heart to the left, was removed. The lack of smothered heart sounds among the classic signs of pericarditis, was explained by the displacement downward and forward of the heart by the pus, which was encapsulated on the right side above and behind the heart. It had collected in a large cavity in the upper right and posterior portion of the pericardium. The adhesions were broken digitally. The pericardium was sutured to the subcutaneous tissues, and a soft tube was put in place, out of contact with the heart. The tube was connected to a drainage bottle protected by a water seal.

The pus contained a Type I pneumococcus in pure culture. The patient received multiple transfusions and sulfapyridine. Because his blood serum showed no circulating antibodies against pneumococcus by the Francis test, he was given 20,000 units of Type I anapneumococcus serum in sufficient quantities and with such frequency as to maintain a positive test, and the chemotherapy was continued. The empyema cavity was aspirated at intervals. The tamponading procedure of aspirations was elected because the child was too ill to undergo even the simple

TABLE 1. *Findings and Results of Treatment.*

CASE No	AGE	SEX	PREVIOUS OR COMPLICATING DISEASE	DIAGNOSIS	SIGNIFICANT CLINICAL FINDINGS	OPERATIVE OR AUTOPSY FINDINGS	OUTCOME	MICRO ORGANISM
1 (1929)	45	M	Pneumonia 3 mo before entry with delayed resolution	Made	Enlarged heart muffled sounds and distended veins	500 cc of pus drained at operation no in topsy	Death	Pneumococcus
2 (1933)	60	M	Hernia (operation) and bronchopneumonia	Suspected	Friction rub enlarged heart and distended neck veins	Lobar pneumonia pleurisy, pericarditis (100 cc of exudate) and enlarged liver (2000 gm) at autopsy	Death	Pneumococcus Type 8
3 (1936)	28	M	Lobectomy for bronchiectasis (several mo before entry) and residual empyema	Made	Enlarged heart paradoxical pulse and positive pericardial tap	420 cc and 135 cc of exudate removed by tapping, pericarditis (950 cc of exudate) and enlarged liver (2200 gm) at autopsy	Death	Pneumococcus Type 8
4 (1937)	65	M	Epidermoid carcinoma of left lung and pneumonectomy	Suspected	Signs of cardiac failure without electrocardiographic changes	Pericarditis (150 cc blood tinged fluid) and enlarged liver (metastasis) at autopsy	Death	Pneumococcus Type 1
5 (1937)	2/3	F	Otitis media pneumonia and empyema (drained)	Made	Enlarged heart dysphagia and positive x ray evidence	400 cc pus drained at operation pericardium well drained at autopsy	Death	Pneumococcus
6 (1939)	1/26	M	Pneumonia otitis media and empyema	Suspected	Precordial friction rub	Pericarditis (few cc of exudate), left pleural exudate and lung abscesses at autopsy	Death	Pneumococcus Type 23 <i>Staphylococcus aureus</i>
7 (1940)	5	M	Pneumonia 3 wk before entry empyema	Made	Enlarged heart and liver, muffled sounds paradoxical pulse positive x ray films and electrocardiogram sternal edema and engorged veins	250 cc of pus removed at operation	Recovery	Pneumococcus Type 1
8 (1929)	18	M	Pneumonia 1 wk before entry pleural effusion	Made	Enlarged heart muffled sounds feeble pulse and distended abdomen	Large amount of pus removed at operation	Recovery	<i>Staphylococcus aureus</i>
9 (1930)	10	F	Osteomyelitis of left thigh (drained) and other foci	Made	Friction rub and positive pericardial tap	50 cc of pus removed at operation well drained pericardium and small necrotic abscess in heart muscle at autopsy	Death	<i>Staphylococcus aureus</i>
10 (1931)	5	M	Osteomyelitis of tibia (drained) and meningitis	Suspected	Terminal friction rub	Pericarditis (75 cc of turbid fluid) myocarditis multiple multiple abscesses in liver, spleen kidneys and lungs, and small patch of endocarditis at autopsy	Death	<i>Staphylococcus aureus</i>
11 (1935)	10	F	Osteomyelitis of femur (drained)	Made	Friction rub absent apex beat, distant sounds and paradoxical pulse	Large quantity of pus removed at operation, well drained pericardial sac at autopsy	Death	<i>Staphylococcus albus</i>
12 (1933)	58	M	Cholecystitis and rupture of subphrenic abscess into pericardium	Not made operated on for embolus	None	Large quantity of pericardial pus at operation, communication with subdiaphragmatic abscess at autopsy	Death	<i>Staphylococcus aureus</i>
13 (1938)	22	M	Chronic osteomyelitis with multiple foci	Not made	None	Pericarditis (50 cc of fluid), abscess in heart muscle and amyloidosis at autopsy	Death	<i>Staphylococcus aureus</i>
14 (1939)	3	F	Abscess of thigh (drained), abscess of lung and pneumonia	Not made	None	Pericarditis (100 cc of fluid), 0.5 cm abscess in right ventricular wall and enlarged liver (8 cm below costal margin) at autopsy	Death	<i>Staphylococcus aureus</i>
15 (1939)	40	M	Pneumonia and sepsis	Not made	None	Pericarditis (15 cc of purulent fluid) and abscess in heart muscle at autopsy	Death	<i>Staphylococcus aureus</i>
16 (1939)	38	F	Chronic osteomyelitis (multiple sinuses)	No pericarditis	None	Myocardial abscess (without exudate in pericardium) and amyloidosis at autopsy	Death	<i>Staphylococcus aureus</i>

TABLE I (Concluded)

CASE NO.	AGE	SEX	PREVIOUS OR COMPLICATING DISEASE	DIAGNOSIS	SIGNIFICANT CLINICAL FINDINGS	OPERATIVE OR AUTOPSY FINDINGS	OUTCOME	MICRO-ORGANISM
17 (1932)	19	M	Pneumonia and lung abscess (?)	Suspected	Muffled sounds and enlarged heart	Pericarditis (100 cc of fluid fluid) interstitial edema in muscle, bilateral lung abscesses and enlarged liver (2800 gm) at autopsy	Death	<i>Streptococcus haemolyticus</i>
18 (1934)	48	F	Chronic sepsis otitis media and skin ulcers	Not made	None (tender right costal margin)	Pericarditis (50 cc of purulent fluid) heart muscle not involved thrombosis of liver and pancreas	Death	<i>Streptococcus haemolyticus</i>
19 (1935)	61	M	Pneumonia and empyema	Suspected	Increased muffled sounds	Pericarditis (100 cc of fluid) in pericardial sac thickened to 4 mm extension from pleura and enlarged liver (2150 gm) at autopsy	Death	<i>Streptococcus haemolyticus</i>
20 (1937)	2	F	Pneumonia 2 wk before entry	Made	Enlarged heart muffled sounds paradoxical pulse and positive x-ray evidence	300 to 400 cc of fluid removed at operation with drainage of retropharyngeal abscess and other foci	Recovery	<i>Haemophilus influenzae</i>

maneuver of trochar thoracotomy. Two weeks after pericardiotomy, the residual empyema was drained by rib resection. The patient gradually improved, and was discharged in good condition on April 27. His health has remained excellent since discharge, and he is leading a normal life.

**Comment.** Pericardiotomy in this case may be regarded as a lifesaving procedure, but should be recognized also as merely an incident in a therapeutic program that would have failed had not the additional aid of immune serum, chemotherapy, transfusions and excellent nursing care been supplied. At the time of operation, the child was seriously ill, but there was no disease of consequence in the lung. The empyema, as well as the pericarditis, was postpneumonic. This sequence is of less serious import than the concurrent appearance of the complication with intra-pulmonary lesions, and may account partially for the favorable outcome. Incidentally, this patient was the third to recover from pneumococcal pericarditis in the hospital records.<sup>8,9</sup> Other cases, even after early and adequate surgical drainage, had always run a discouraging course of continued weakness and increased infection, and after a period of 2 or 3 weeks, the patients died. The presence of empyema as an additional burden has been cited frequently in the literature as highly unfavorable prognostically.

Pericardiotomy was performed in 2 other patients with purulent pneumococcal pericarditis (Cases 1 and 5, Table 1). The drainage of 500 cc of thick pus in Case 1 and 400 cc in Case 5 may have resulted in temporary periods of improvement, but failed to change the progressive course of the disease. Both cases are illustrative of the steady decline in general condition that often typified cases of pneumococcal pericarditis, even after drainage, in the years before chemotherapy and immunotherapy became available. The patients in the remaining 4 cases of pneumococcal pericarditis died without operation.

The pericarditis in 9 cases was due to *Staphy-*

*lococcus aureus* infection, and operation was performed in 3 of these cases, with recovery in 1. Pericardial drainage was without question a lifesaving procedure in this last patient (Case 8), but was postponed until he was almost moribund. The error was largely due to failure to suspect the diagnosis, for the recorded observations indicated the presence of pericardial effusion for many days before it was recognized clinically. Although drainage of the pericardial cavity was adequate in each of the other 2 operated cases (Cases 9 and 11), infection elsewhere was too severe and extensive for a fatal outcome to be prevented. An interesting finding in 1 case was an abscess in the heart muscle, which Nikolaew<sup>10</sup> also considered. Similar myocardial abscesses were discovered in 4 of the 8 fatal staphylococcal infections. In another case (Case 16) worthy of mention in this series, an abscess was found in the left ventricular wall containing thick yellowish pus and presenting against the epicardium but not accompanied by exudate within the pericardial cavity. The occurrence of an actual abscess in the myocardium, without an exudative response in the immediately adjacent pericardium, must be extremely rare.

Three patients died of streptococcal infection, and no operation was performed in this group. One case (Case 19) illustrates the fact that signs of pericardial effusion can at times be produced by a small quantity of fluid, only 100 cc. being found at autopsy. Inability of the pericardium to dilate, owing to preceding inflammatory fixation in association with empyema, is the probable explanation.

In 1 case (Case 20) of influenza-bacillus infection, the patient survived following pericardiectomy.

### DISCUSSION

Even a casual perusal of these cases reveals that suppurative pericarditis finds its most frequent precursors in staphylococcal and streptococcal bacteremia and in pneumonia. Of the 20 cases, 12 were preceded by pneumonitis or pneumonia, 6 by osteomyelitis, 1 by cholecystitis, and 1 by mastoiditis. In the case following cholecystitis (Case 12), the pericardial infection was obviously secondary to perforation of a subphrenic abscess into the pericardium. Ochsner and DeBailey,<sup>11</sup> in reviewing 3608 cases of subphrenic abscesses, found a perforation into the pericardium in 71.

One case of streptococcal pericarditis (Case 19) was probably due to direct extension from a nearby streptococcal abscess in the pleura. In the 2 other cases, the method of metastasis, whether by extension directly, by blood stream or by lymphatic flow, is uncertain. The coexistence of myocardial abscesses in 4 staphylococcal cases and the presence of myocardial abscess in 1 case without concurrent pericarditis indicate the poor prognosis that must be anticipated in staphylococcal pericarditis even after drainage of the pericardium. Such abscesses were not found in infections from other organisms. In none of these cases had the abscess perforated either into the ventricle or into the pericardium, and the case of myocardial abscess without pericarditis suggests that pericardial effusion need not be considered a sequel to abscess. Unfortunately, in no cases in which a myocardial abscess was discovered post mortem had an electrocardiogram been taken. Attention is called particularly to the diagnostic help that might be available from this laboratory method, because in these cases electrocardiographic changes seem to be likely.

Suppurative pericarditis occurred in 12 patients under thirty years of age and in 8 over thirty. Fourteen patients were males, and 6 were females. These figures parallel very closely those derived for age and sex incidence from collected statistics.

### Diagnosis

The difficulty of diagnosis is apparent from the difference of incidence in the figures of the pathologist and the clinician. However, the likeliest cause of this discrepancy is the failure of clinicians to keep in mind the possibility of pericarditis and to seek the signs that suggest it in any case of infection not progressing satisfactorily.

Frequent careful evaluation of the area of cardiac dullness and the character of the heart sounds

is extremely valuable in the early detection of this complication. Muffled heart sounds due to accumulated fluid are a sign that can be supported by x-ray examination, and fluoroscopy is more helpful than film. Not only can diminished or absent pulsations be observed, but alteration in configuration of the cardiac shadow with changes in position can be discovered, as Holmes<sup>12</sup> pointed out; this is a very useful sign.

Kymography furnishes information about the amplitude and character of cardiac pulsations and thus indicates tension within the pericardial sac, but the data from kymography are not always conclusive. The diminution of pulsations is not a sign restricted to pericardial effusions, and Freedman<sup>13</sup> has also observed it in decompensated hearts and in cases of myocardial disease. Berner<sup>14</sup> describes the discrepancy between pulsations of the ventricular wall and those of the aortic knob as being of differential value. In pericarditis, the pulsations of the knob are very distinct, with decrease in movements of the heart itself, whereas in decompensation the weak heart action has an equal effect on the pulsations of both structures. Sufficient observations are not yet available to allow evaluation of this sign.

A number of authors<sup>15-17</sup> have considered the electrocardiographic changes occurring in acute pericarditis. The changes consist in elevation of the RST segments in Leads 1, 2, 3 and 6, and a depression in Leads 4 and 5. These alterations are usually transient, and last not longer than two weeks, after which the most constant change is an inversion of the T waves. These abnormalities can be confused with those of infarction of the myocardium, but when the electrocardiogram is carefully studied in conjunction with the clinical facts it may contribute valuable help. The changes are believed to be due to alterations in the subepicardial muscle layers, and not to the pressure of the exudate, and they are therefore of little value as an actual indication for operation.

Auxiliary signs of great diagnostic value, when present, are a paradoxical pulse, engorged neck veins, an enlarged liver, sacral edema and a pericardial friction rub. The last is transitory. Its presence means much, its absence little. Some degree of cyanosis and respiratory distress is almost constantly observed. The paradoxical pulse is not always easy to feel, but with the help of a blood-pressure cuff the difference during inspiration and expiration can be made more obvious. When the pressure in the cuff is gradually raised, one finds a point where the pulsations during inspiration will just be suppressed.

### Treatment

The mechanical problems of pericardial effusion are different from those encountered in pleural effusion. In the latter, the tendency is to delay operation until the fluid becomes frankly purulent, and until one can expect that enough adhesions have been formed to prevent collapse of the whole lung. The quantity of fluid is, as a rule, not the deciding factor. In pericardial effusion, however, it is mainly the pressure of accumulated fluid that jeopardizes the life of the patient. To control the situation with aspiration is less satisfactory and more dangerous than in pleural effusion. It sometimes happens that the pus is present in a pocket behind the heart, as was true in Case 7 and attempts to aspirate in such conditions will necessarily fail and carry a great risk of injury to the heart. A few cases have been reported in which repeated taps were sufficient to cure even a purulent pericardial effusion,<sup>9, 10</sup> but pericardiotomy is the more reliable procedure. For example, 1 patient (Case 3) was treated by pericardial aspiration because the fulminating progress of the infection and the desperate condition of the patient caused the surgeon to think that pericardiotomy would be a procedure of greater magnitude than the patient could undergo safely. Perhaps so, but it should be noted that 950 cc. of fluid remained in the pericardium after aspiration, and that needle aspiration almost uniformly fails to save the patient.

It is difficult to estimate how much fluid must accumulate in the pericardial cavity to create signs of cardiac tamponade. Slowly developing exudates can reach a quantity of 600 to 700 cc., and sometimes even more, without pressure signs. However, when fluid accumulates rapidly, as with blood in heart wounds, 100 to 200 cc. can give symptoms of severe tamponade. In acute pericarditis, a relatively small amount of fluid can interfere significantly with the circulation. White<sup>18</sup> stresses the engorgement of the veins and enlargement and tenderness of the liver as early signs of pericardial effusion. That this can occur with relatively small amounts of exudate can be seen in 3 cases (Cases 17, 18 and 19), in which only 100 cc. of exudate was present and in which the liver was enlarged and heavy, with the edge well below the costal margin. In cases in which the fluid has not become purulent, one can expect a change every day, and even in these, pericardiotomy is considered by some<sup>6</sup> to be better than waiting, with or without aspiration.

Opening the pericardium is not a difficult procedure, and enough experience has accumulated to show that exposure of the heart to atmospheric

pressure is almost without danger, and certainly less dangerous than exposure to a positive pressure in a closed pericardium. Whether or not a pericardial tap should be performed before operation depends largely on the certainty of diagnosis. The needle is still a blind instrument, and accidents have been reported, however, applied with skill and care, such a tap may yield valuable information. Every effort should be made to avoid infection of the pleura, and for this reason the parasternal approach seems to be the most logical. The technic of pericardiotomy naturally varies with the surgeon. The left parasternal approach used in Case 7 is recommended as simple, safe and effective. Bigger and Bunch<sup>7</sup> also advocate this approach. Moore<sup>19</sup> describes the advantages of a posterolateral dependent drainage, which we believe carries great risk of infecting the left pleural cavity. Gonnard<sup>20</sup> describes median and subcostal epigastric routes of approach, which are satisfactory.

### Prognosis

The prognosis of purulent pericarditis depends largely on the collateral foci of disease, untreated purulent effusion into the pericardium, however, has a 100 per cent mortality. When operation is performed, the chances for recovery increase to about 40 or 50 per cent. From the literature, it seems that pneumococcal pericarditis has a slightly better prognosis, but the present group is too small to warrant any suggestion in this regard.

Fear formerly existed that these patients would develop constrictive pericarditis. This has not happened, however, and probably need not be anticipated unless the effusion is due to tuberculosis. Operation in one case (Case 8) in this series dates back to 1929, and this patient is now in excellent health. A second patient (Case 20) is also in good health three years after operation. A third patient (Case 7) was treated only sixteen months ago and is in excellent condition, but the period of observation is too short to be called an end result.

### Cause of Death

The patients who were not operated on died for various reasons. In many, the bacteremia was overwhelming, and in others the small amount of fluid could scarcely have been responsible for death. In some of the cases, however, early pericardiotomy might have changed the course of events.

### SUMMARY AND CONCLUSION

Three cases of purulent pericarditis are described in which cure was obtained by operation. In the description of a case of purulent pneumococcal pericarditis emphasis is placed on the com-

bination of surgery, immunotherapy and chemotherapy as being responsible for the recovery. Sixteen other cases of suppurative pericarditis are described.

In 5 cases of staphylococcal pericarditis, an abscess was found in the heart muscle; a suggestion is made concerning electrocardiographic studies in such cases.

It is shown that in purulent pericarditis small amounts of fluid, by their rapid accumulation in an unyielding pericardial sac, can give severe signs of heart tamponade.

Problems of diagnosis and treatment of suppurative pericarditis are discussed.

It is concluded that a less pessimistic attitude toward suppurative pericarditis is possible in the light of recent advances in immunology and chemotherapy.

## ACTIVITIES OF THE BOSTON HEALTH DEPARTMENT\*

G. LYNDE GATELY, M.D.†

BOSTON

IT is significant to note that men of influence in the early history of Boston gave attention to the prevention and control of disease. Health, history and heroes are bound in one. Our predecessors blazed a trail that has not only kept Boston in the forefront of American municipalities in matters affecting public health, but has left a path that sanitarians of other cities in later years have safely followed.

Many of the men of those early days that we remember through our school histories have their names in the annals of health in this section of the Commonwealth. I have in mind Samuel Fuller, Governor Winslow, the Reverend Cotton Mather and the president of Boston's first Board of Health, Paul Revere. Dr. Samuel Fuller came over on the Mayflower in 1620, and his wife, Bridget Lee, acted as nurse in his professional work in ministering to the colonists.

As early as 1639, Massachusetts provided for the registration of births, deaths and marriages.

In 1647, an act of the legislature against the pollution of Boston Harbor was passed. Statutes that required the isolation of the sick and inter-

esting local regulations adopted in accordance therewith were promulgated in Boston and Salem as early as 1678, so that the attempt to check the spread of communicable diseases is nothing new.

In 1721, the efforts of Zabdiel Boylston and the Reverend Cotton Mather to provide inoculation against smallpox were treated with derision, but Dr. Boylston was later rewarded by being made a fellow of the Royal Society of London.

The Acts of 1799, Chapter 10, empowered "the Town of Boston to choose a Board of Health for removing and preventing nuisances."

In 1816, a law was passed by statute to permit the inhabitants of Boston to choose one able and discreet person from each ward to be a member of the Board of Health.

On December 2, 1872, the mayor was vested with the power to appoint a board of three commissioners to exercise the functions of the Board of Health.

The activities of the Board of Health were originally much more extensive than they are at present; for example, they included the collection of ashes and garbage, which was finally delegated to the Department of Public Works, where it properly belongs.

\*Presented at the annual meeting of the Boston Health League, April 23, 1941.

†Commissioner of Health, City of Boston.

In 1894, Boston was the first city in this country or abroad to establish, through its health department, a system of daily medical inspection of children in all public schools. At present, the Health Department prepares daily a list of all the communicable diseases reported for the calendar day, a copy of which is sent to all schools, hospitals and interested institutions in the city. In this way, the School and Health departments cooperate in the proper control of such diseases.

Aside from these functions, which properly belong to the Health Department, there are in Boston certain other phases of health work that in other cities are under the direct supervision of the health departments, but that in Boston are under the control of separate departments. I refer to the registration of births, deaths and marriages, to the hospitalization of diseases of all kinds, particularly communicable diseases and tuberculosis.

The Health Department is composed of the following divisions, as provided by city ordinance: Vital Statistics, Communicable Diseases, Laboratory, Tuberculosis, Child Hygiene and Health Units, Housing and Sanitation, and Food. The Milk Inspection Service is regulated by statute law. The following services have been established within the department: dental, nursing, health education, dairy and abattoir. The department sponsors three WPA projects: an eye conservation program, a nursery school program, carried out on the roofs of the Health Units, and a physical examination program for welfare recipients and WPA workers.

Each of the major divisions is now headed by a deputy commissioner. Since each unit is a decentralized health department, I am desirous of changing this setup, so that there would be only one deputy health commissioner, who would be in charge of the Division of Child Hygiene and Health Units. The rest of the department should be divided into bureaus, with a director in charge of each.

The following are the activities of the major divisions of the Boston Health Department:

*Division of Communicable Diseases* This division deals with the control of reportable diseases, including work incident to lapsed and incorrigible cases of syphilis and gonorrhea and the follow-up of cases for required treatment and hospitalization. Cases of food poisoning are investigated by this division, which also furnishes death certificates in cases in which the medical examiner declines jurisdiction. This division approves licenses to conduct maternity hospitals and homes for the reception of women during pregnancy and in-

vestigates day nurseries. Supervision of the rabies problem by the quarantine of animals is carried out as one of its functions. The veterinarians of this division make annual inspections of cattle, goats, sheep, swine and fowl for the purpose of detecting the presence of contagious disease in animals.

*Laboratory Division* The laboratory provides diagnostic laboratory examinations for diphtheria, tuberculosis, gonorrhea, syphilis, dysentery, malaria, streptococcal infections and Vincent's disease; it performs guinea pig inoculations for the determination of diphtheria virulence and of the presence of tubercle bacilli in body fluids, and it conducts bacteriologic examinations of raw milk, water from swimming pools and beaches, and food. Suitable outfits are provided to physicians, clinics and hospitals for collections from patients of specimens or materials to be submitted to the laboratory for bacteriologic, microscopic or serologic examination. The laboratory is also the distributing center for Boston of the biologicals produced by the Massachusetts Antitoxin and Vaccine Laboratory. The volume of annual performance has increased notably in serologic procedures, owing to the venereal disease program. The pending standardization of all laboratories by the Massachusetts Department of Public Health has resulted in an evaluation study of both Wassermann and Hinton findings in a series of routine blood specimens, with the possibility that the latter method will ultimately be adopted as an accepted routine test. In 1940, about 63,000 examinations were made.

*Tuberculosis Division* The aim of this division is the discovery of cases of tuberculosis and the supervision and disposition to sanatoriums of cases that require treatment. Thirteen diagnostic clinics have been established at strategic points throughout the City. There are twenty-three weekly sessions. The clinics are manned by a group of fifteen physicians, and the attendant service is supplied by the Nursing Service. When hospital disposition is recommended, each case is looked into by the settlement investigator. Boston settled cases are admitted to the Boston Sanatorium, and State settled cases are sent to state sanatoriums. Two pneumothorax clinics are held each week. X-ray films are taken of every patient on the initial visit, and repeat films are often necessary. This X-ray service operates in eight units, and in addition carries out necessary X-ray and fluoroscopic study at the pneumothorax clinics. A weekly nose and throat clinic is held at the Concord Street Unit. Lamp treatments are given to patients with lymph node infections, Wassermann tests are made on all adults, and Von Pirquet skin reaction

tests on all up to seventeen years. In 1940, there were 1245 cases of pulmonary and extrapulmonary tuberculosis (1030 resident and 215 non-resident), and 167 cases of childhood-type tuberculosis. There were 456 deaths from pulmonary and extrapulmonary tuberculosis (419 pulmonary and 37 extrapulmonary). There were 904 admissions to hospitals. In the clinics, there were 22,510 examinations, 6698 x-ray films, 2031 Von Pirquet tests, 1270 Wassermann tests and 639 lamp treatments. There were 3834 pneumothorax treatments.

*Division of Child Hygiene and Health Units.* During the past year, twenty-nine weekly conferences were held in the seventeen baby and pre-school stations located in the Health Units, municipal buildings and settlement houses and staffed by pediatricians from Harvard, Tufts and Boston University medical schools. The medical inspectors participate in the conferences in the Health Units. Six thousand four hundred and eight newborn babies were registered at our clinics last year, as well as 308 children from one to two years of age, and 260 between two and five years. The number of newborn registered represents about 40 per cent of the total births in 1940. Medical inspectors made 224 visits to day nurseries. The physical condition of the children was checked, and vaccinations and immunizations were performed.

*Division of Housing and Sanitation.* The following are some of the activities of this division: routine inspections of tenement houses, three-family houses, private lodging houses and public lodging houses; observation of offensive trades; control of smoke and fume nuisances as related to public health; enforcement of the law relating to surfacing, grading and draining of private alleys; enforcement of building laws relating to public health; supervision of swimming pools, wading pools and beaches, including the taking of samples of water for analysis; rat and vermin control; supervision of conditions along the waterfront; licensing and maintenance of dumps; and survey of plumbing in buildings, including cross connections and inspection of water in dwellings.

*Food Division.* The work done in this division includes control and supervision locally over the sale, production and manufacture of food, drugs and so forth. The Food and Drugs Law, to prevent misbranding of food and drugs, is enforced by this division. Wholesale and retail store inspection, market and bakery inspection, and regular inspection of food establishments requiring licenses are made by inspectors of the division. The control of vehicles used by itinerant peddlers of fish, fruit and vegetables, as well as the fruit and

vegetable terminals and the Boston Fish Pier, comes under it. The City is divided into fourteen districts, and the districts are divided into routes. The inspector is able to cover one route each working day. The "Saturday" market is efficiently handled by this division. The stands and peddlers must pass a rigid examination, which also applies to meat and poultry. Co-operative work is also done with the United States Food and Drug Administration.

*Dental Service.* Dental clinics are held daily in eight health units and two stations from 9 a.m. to 4 p.m. (Saturdays from 9 a.m. to 12 noon). Three days a week are allotted to the children of the public schools, two days to the children of the parochial schools, and Saturday morning is an open clinic for preschool children and emergencies. The attendance during 1940 was 75,523; the number of patients was 38,755; and the number of operations was 127,606.

The regular dental personnel is augmented by the services of five dentists and two hygienists of the WPA.

*Nursing Service.* A policy of generalized nursing has been carried on, and the nurses are assigned to various districts on the basis of need. Under this plan, nursing service is provided for the Communicable Diseases, Child Hygiene and Tuberculosis divisions, including clinic service and necessary home visits. The nurses also give service to parochial schools and day nurseries.

Nurses' visits to cases of communicable diseases in 1940 amounted to 26,710. Visits in the field include follow-up visits on all children attending the twenty-nine weekly conferences held in seventeen different stations throughout the city; and visits to newborn babies to ascertain their need of health supervision were also made. On December 31, 1940, there were 26,727 children under the supervision of our nurses.

Nursing service is given to all but one of the forty-eight parochial schools in Boston, with a school population of 26,275. Five thousand eight hundred and ninety-two visits were made to parochial schools in 1939, and 5210 in 1940.

Nurses assist in the selection and transportation of children to and from the dental clinics.

Twenty-nine day nurseries and nursery schools are given health service by the nurses, and 1286 visits were made to those groups in 1940.

All reported cases of tuberculosis and their contacts are supervised by the nurses until there is some good reason for discontinuing this service. On December 31, 1940, 27,239 patients and contacts representing 8582 families were under the supervision of the nurses. There were 9782 dis-

charges during the year, but there were also 1116 readmissions and 4525 transfers from one district to another. In 1940, the nurses made 123,792 visits to tuberculous patients and their contacts.

Field training is provided for students attending the School of Public Health of Simmons College.

I consider it worth while to correlate the evolution of Boston's public-health program during the last fifty years with the improvement in health conditions that is reflected by the constant reduction of morbidity and mortality, and I shall present some vital statistics from the reports of the Boston Health Department, which furnish a reasonable cross-section of prevalent health and disease conditions in many parts of the United States for the periods enumerated. The mortality rates from specific causes may be considered typical, by and large, for the country as a whole.

Particular attention is called to the encouraging figures that reveal the halving of the general death rate during the last half-century. It is also pleasing to call attention to the tremendous reduction in the tuberculosis death rate and in the deaths from diphtheria, typhoid fever and scarlet fever. Contrasted with this improvement, deaths from heart disease have more than doubled, and those from diabetes and cancer have almost tripled.

What is the comparative picture? In 1940, there were about 50 deaths per 100,000 inhabitants from pulmonary tuberculosis, 0.8 from scarlet fever, 0.3 from diphtheria, and 0.1 from typhoid fever.

In 1890, with a population of approximately 450,000 as contrasted with the present population of about 800,000, there were actually 400 deaths in Boston from diphtheria, as against 2 in 1940; 41 from scarlet fever as against 9; and 155 from typhoid fever as against 1. If the infant death rate prevalent in 1890 were applied to the number of live births in 1940, there would have been 2600 deaths of children under one year of age, as against the 764 that actually occurred.

What have been the results of this half-century of public-health effort in Boston? As already mentioned, the span of life has been materially lengthened; the death rates from all causes have been almost halved; the infant mortality rate has been reduced by 75 per cent, that of tuberculosis by 89 per cent; diphtheria and typhoid have almost been eliminated as causes of death in the community; deaths from scarlet fever have become negligible.

What have been the changing practices that have brought about this remarkable improvement?

Hermann M. Biggs, to whom we owe a great deal for the development of administrative technic in the field of public-health administration, proclaimed that public health was purchasable, and that within reasonable limitations, communities might determine their own death rates. By this statement, he meant in substance that the wise expenditure of adequate funds for the conduct of essential public-health activities would markedly control the prevalence of preventable diseases and deaths from many causes. What are these activities that he had in mind, and what part have they played in influencing the health of the American people? I have already mentioned the significant effect of the application of sound procedures for the sanitation of the environment, the protection of water and milk supplies and the control of communicable diseases. The place of the laboratory as a significant component part of a modern health department has been amply illustrated. The value of immunologic agents has been demonstrated beyond measure as a factor in the prevention of disease.

Very fortunately for organized society, this century has been marked by a number of significant public-health movements, which have required the participation of the individual. The child-hygiene movement, the campaign for the control of tuberculosis, the mental-hygiene movement and the social-hygiene movement, waged by official and voluntary agencies, have stimulated the imagination of the American people, and have resulted in higher standards of individual and community health. Clinics of various types, carrying on the functions in the above-mentioned fields and having for their objectives the prevention and control of disease, have become increasingly utilized by armies of people, who have demonstrated by their reaction the belief that an ounce of prevention is worth a pound of cure.

One should call attention to the significant relation between satisfactory prenatal care and maternal and infant welfare. Studies carried on in Boston have proved that the death rate among expectant mothers receiving adequate prenatal care is about half that among those lacking such medical supervision. Prenatal care has done much to reduce the hazards of the toxemias of pregnancy, injuries at birth and prematurities, and to lower deaths among infants. There is, however, much room for further improvement in reducing deaths occurring during the first month of life.

Both voluntary and official agencies have concerned themselves with the problem of infant, pre-school and school-child health. Milk stations and

baby and preschool clinics have served as the headquarters for the dissemination of information, and for the education of mothers in the very best methods for keeping children well. Among the administrative methods for the conduct of this work has been a co-operative plan developed in Boston, between the Health Department and the Harvard, Tufts and Boston University medical schools, whereby pediatricians from the teaching staffs man the clinics and are reimbursed by the Health Department. Advantage is taken of the presentable opportunity for teaching medical students preventive pediatrics.

It is in the fields of child health and tuberculosis that the public-health nurse has made a lasting contribution. Newborn babies are visited shortly after birth by nurses of the Health Department, and mothers are urged to take their babies either to their own family doctor or to the clinic for periodic medical supervision. Here, children are examined, vaccinated against smallpox, and immunized against diphtheria. Breast feeding is stressed, and whenever possible the use of pasteurized milk and the preparation of the proper formulas are taught. When children arrive at the preschool age, the so-called "neglected age," every effort is made to maintain the continued interest of the parents in the physical and mental health of the child. There is, however, room for much further progress in this age group.

One is familiar with the frequency with which faulty teeth, defective vision, defective hearing, malnutrition, faulty posture, functional or organic heart disease and occasionally tuberculosis are found among the school-child population. Large sums are being spent in the United States for the medical inspection of schools and physical examinations for the discovery of remediable defects. Emphasis should be placed on the value of increasing efforts for the correction of defects found. An example of excellent service in this field is the program carried on by Dr. James A. Keenan, his school physicians and nurses in the Boston Public Schools; the Health Department assumes the responsibility for medical inspection in the parochial schools.

The care of the mouth and primary teeth is receiving fitting recognition. It is hoped that what is being done for children today in the way of preventive dental care may bring about higher standards of dental health for the American people. An outstanding example of municipal interest in this field is the program of the Health Department, whereby a corps of approximately

twenty dentists and ten hygienists of the Forsyth Dental Infirmary carry on prophylactic dental service in the Health Units. This personnel is reimbursed from tax funds.

Attention is being given to the subject of proper nutrition as a factor in normal growth and development, to the eradication of faulty food habits and to the establishment of proper and well-balanced diets.

The attack against tuberculosis represented what may be termed the second important public-health effort at the beginning of the present century. Case-finding, the isolation of the infected person, the rounding up of contacts who have been exposed, occupational adjustments and pneumothorax are all a part of the modern campaign for coping with this problem. Today, every health department of appreciable significance either maintains, or sees to it, that there exist in the community adequate facilities for tuberculosis control.

For a number of years, the subject of the control of venereal diseases was approached, except in rare cases, with much diffidence and hesitation. Gonorrhea and syphilis represent an important public-health problem. Stimulated by the efforts of the National Society for Social Hygiene, and more recently by the vigorous challenging efforts of Surgeon General Thomas Parran, and with the assistance of federal funds, a worth-while program is constantly making further progress. The Massachusetts Department of Public Health, with the aid of the above-mentioned funds, not only assists in the maintenance of a number of venereal-disease clinics, but stimulates the upholding of adequate standards. Of particular significance is the organization of facilities for rounding up the lapsed cases.

During the present century, there has been an increasing recognition of the relation of housing to health and the control of disease. It has been recognized that adequate light, air and ventilation and the avoidance of overcrowding are minimum requirements in the field of human needs.

There is a need for an increased recognition by those responsible for community health of the problems of mental hygiene and mental disease. A ray of hope is offered by the expansion of the child-guidance clinics conducted under official or voluntary auspices, which deal with the problem of faulty habits in children and the need for the improvement of the environment to which the child is exposed. Certainly, the tragically high prevalence of mental disease should focus attention on the need of more prevention.

Vigilant health officers appreciate the value of an understanding by the public of the functions and objectives of the Health Department. Healthful living needs interpreting in simple, understandable language. The spoken word in the clinic, in the lecture hall and over the radio, and the visit of the public-health nurse can be opportunely utilized for educational health propaganda. The leaflet, the poster, the pamphlet may all serve the useful purpose of making people more health-minded. Here and there, health educators employed by health departments are living examples of changes in public-health practice from police methods to education.

As deaths from preventable causes have been lessened and the average span of life increased, many persons are living to middle and later life, with a consequent increase of the diseases prevalent in the older groups. Among these illnesses are cardiovascular disease, cancer and diabetes. This newer public-health problem should be the concern of the health officer. Although this does not imply that he must necessarily conduct medical activities for the treatment of these diseases, it is his obligation both to educate the public in methods for their control and to see that there are in his community an organized medical profession, clinics and hospitals to cope with these problems.

The health officer today integrates the efforts of administration—the findings of the statistician, the medical inspector, the public-health nurse, the milk, food and sanitary inspector, the laboratory technician and the school physician—with those of the representatives of the voluntary health agencies. Today, in cities of varying size, health services are frequently conducted on a district basis. Radiating from the health centers, which were founded to bring together under one roof in a spirit of service and of team play all concerned with the problem of health and welfare, these services attempt to present a united front against sickness and death.

Statistical figures that corroborate the assumption that improvements in health result from changes in public-health practices tell but a part of the story. Even more can be done. There are still too many deaths from preventable causes. Health workers can add more years to the span of life and improve the span of health, since the knowledge and methods at their disposal possess rich, lifesaving values. They must create, by education and by the conduct of adequate programs, a greater desire on the part of everyone for life's most treasured possession—optimum physical and mental health.

Since I have been health commissioner, I have been very fortunate because of the establishment of the Advisory Council, composed of leaders in the fields of public health and medicine and of representatives from the voluntary agencies, under the able leadership of your president, Dr. George C. Shattuck. Each of these leaders is to make a special study of a division or service of the Health Department, and will make recommendations that will result, I am sure, not only in improvement of efficiency, but also in raising the standard of performance. This council has had two meetings so far, and I can honestly report a true spirit of co-operation and progress in the right direction.

In the Laboratory Division, we are making some special studies in whooping cough, and also working out a new method for gonococcus culture and diagnosis as a part of the program for the control of venereal disease. In the Milk Inspection Service, we have succeeded in obtaining the co-operation of all the milk companies supplying Boston, so that by July 1 of this year, we should have 100 per cent pasteurization of the Boston milk supply.

In the interest of national defense, the Boston Health Department, through its Laboratory Division, has recently co-operated with the Government in performing thousands of blood tests for selectees and the National Guard. In conjunction with the Massachusetts Department of Public Health, the Tuberculosis Division has x-rayed several hundred selectees. This year, I earnestly hope to set up, with the co-operation of the State Department of Public Health and with the help of federal funds, a greatly improved and enlarged health-education program, as well as a much more comprehensive program for the control of venereal disease.

I compliment all the private and voluntary agencies in the City of Boston, many of which are housed in the Health Units, for I honestly believe that in no other city is the relation between the Health Department and these agencies more pleasant and more harmonious.

It would be in poor taste for me to make any preposterous claims for the Boston Health Department, but I should like to emphasize that I know of no perfect performance by any health department, and I am of the sincere conviction that the combined performance of the Boston Health Department and the voluntary health agencies compares favorably with that of any other large city in the country.

## SPONTANEOUS MEDIASTINAL EMPHYSEMA\*

CHARLES W. STYRON, M.D.†

BOSTON

SPONTANEOUS mediastinal emphysema should always be considered in the differential diagnosis of pain in the chest, because if the diagnosis is missed, a grave prognosis may be given for a benign condition.

The history of the pain associated with spontaneous mediastinal emphysema may well be consistent with coronary thrombosis, pericarditis, ruptured or dissecting aneurysm, mediastinitis, pulmonary embolism and spontaneous pneumothorax.

The syndrome may occur at any age, usually in a healthy person, with or without exertion. The onset is frequently alarming and dramatic, with sudden precordial or substernal pain, shortness of breath and cyanosis. The pain may be slight or quite severe, and it may be necessary for the patient to remain in one position for relief. He may feel or hear a peculiar grinding or crunching in his chest with each heart beat, with swallowing or with change in position. The pain may gradually subside within a few hours or may persist with exacerbations and remissions for a variable period. The patient may recover completely, only to have the same train of symptoms recur after a few weeks, months or years.

On physical examination, the patient usually appears comfortable except for the pain. The temperature, as a rule, is normal, with normal or slightly elevated pulse and respirations. Dyspnea and cyanosis are sometimes present. Certain important physical signs are found. Dullness to percussion over the left border of the heart is diminished or absent. Bubbling, crunching and gurgling to-and-fro sounds are heard over the precordium. These sounds are altered by change in position, and may cease with the disappearance of pain. Signs of pneumothorax may be found, but the pneumothorax is frequently so small that changes are not apparent on physical examination. Occasionally, air may appear under the skin of the neck or above the clavicles.

The diseases that are confused with spontaneous mediastinal emphysema are, as a rule, readily differentiated. The history alone may be sufficient to make the diagnosis, particularly if the patient is conscious of these gurgling, crunching sounds, with relief on change in position. The presence

of air in the subcutaneous tissues of the neck or periclavicular regions is helpful. Previous adjacent operation may be the cause of mediastinitis or pericarditis, and infection or operation at a distance, by subsequent thrombophlebitis, may produce pulmonary embolism. Small infected emboli may produce mediastinitis, with or without concomitant pulmonary infarction. The presence of fever and leukocytosis and characteristic electrocardiograms serve to differentiate coronary thrombosis and pericarditis. X-ray examination may be essential, however, if obvious signs are not brought out on the first examination. Subfascial emphysema, often present after artificial pneumothorax, need not be confusing.

Hamman<sup>1, 2</sup> is credited with calling attention to the uncommon syndrome that bears his name. He was able to prove some of his cases either by x-ray or by subsequent clinical course, in addition to the characteristics mentioned above. Morey and Sosman<sup>3</sup> reported a case in a young man in which there was a small pneumothorax. They stated that the disease may occur as a result of coughing, in asthmatics, in labor, after trauma and operation, and following artificial pneumothorax. They mentioned the possible necessity of incising the neck to release the accumulated air. By overdistending the lungs of cats and other animals with a truncated catheter, Macklin<sup>4</sup> has shown that air dissects into the perivascular sheaths and travels along these sheaths to the mediastinum, thus producing a mediastinal pneumothorax. Clinically, this condition may occur when the alveoli are subjected to abnormal pressures in the closed method of anesthesia, in infection with bronchial or bronchiolar obstruction, and in pathologic conditions of the heart and great vessels. The dissection of air may extend to the opposite lung, to the abdomen (to produce a pneumoretroperitoneum), to the neck and to the periclavicular regions. Scott,<sup>5</sup> Faulkner and Wagner<sup>6</sup> and Caldwell<sup>7</sup> have written on the subject. Caldwell mentioned a traumatic case due to a stab wound, in which the patient was found to have typical signs the day after the accident.

## CASE REPORTS

CASE 1. J. C., a 33-year-old man, was quite well until April 15, 1940, when, while walking, he was seized by a gripping pain in the midscapular region that radiated

\*From the First Medical Service, Boston City Hospital.

†Formerly, house officer in medicine, Boston City Hospital; fellow in medicine, George F. Baker Clinic, New England Deaconess Hospital.

around to the precordium, up to the left shoulder and, finally, down the left arm to the wrist. The patient was unable to get his breath, felt weak, and was forced to sit down. He dared not move at the time for fear of aggravating the pain and, indeed, feared that he was going to die. The pain lasted about 3 hours, at the end of which he was brought into the hospital. He remembered having had a somewhat similar pain 12 years previously.

Physical examination showed an asthenic young man lying quietly. He was apprehensive. The face was flushed, the tongue was tremulous, and the trachea was in the midline. The left chest was somewhat full anteriorly. Expansion was equal, and both lung fields were resonant. Breath sounds were normal. The left border of the heart was 9.5 cm from the midsternal line. The heart rate was regular and rhythmic and a faint systolic murmur was heard at the apex, a faint transient grating sound was heard in the tricuspid area.

The blood pressure was 140/80, the temperature 97.8°F, the pulse 65, and the respirations 22.

At the time of examination, the patient was thought to have a coronary occlusion. He continued to have substernal pain off and on for 2 days. On the 3rd hospital day, the patient complained of a to-and-fro thumping noise. The sound was easily heard at a distance of several feet from the chest wall. When a stethoscope was placed on the precordium, very loud crunching bubbling sounds were heard. The sounds altered markedly with change in position, and were best heard on the left side. The same phenomenal sounds were heard at a later time. In the course of a few hours, the sounds disappeared permanently.

Three electrocardiograms at intervals of several days were normal. Westergren sedimentation rates at 3-day intervals were 1, 6, 8, 6, 4 and 5 mm at the end of 1 hour. The white-cell count was never over 6800. Serologic tests were negative. The nonprotein nitrogen was 26 mg per 100 cc. A foot x-ray film of the chest was within normal limits.

The patient was followed at monthly intervals for a year and had no recurrence. Repeated electrocardiograms were normal.

Although no x-ray evidence of a pneumothorax was found, it was concluded that the signs described above were so typical as to furnish unmistakable evidence of mediastinal emphysema. Furthermore, the clinical diagnosis was certainly supported by laboratory studies.

CASE 2 F.M., a 22-year-old man, was well until August 31, 1940, when, while walking along the street, he felt a stabbing precordial and left-sided chest pain. He became short of breath and had to sit down for relief.

He was brought to the hospital. Following arrival, he remained fairly comfortable.

The patient seemed rather frightened but felt generally well. His color was good. The trachea was questionably deviated to the right. Expansion of the thorax was equal. The lung fields were resonant. Breath sounds were slightly diminished high in the left axilla and at the left apex posteriorly. The left border of the heart was 8 cm from the midline in the 5th interspace. With the patient in the recumbent position, the heart sounds were regular and rhythmic, with a very faint scratching sound characteristic of a friction rub. However, when he was turned on the left side, loud, crunching, bubbling, gurgling, to-and-fro sounds were heard and were audible to the patient. The sounds were easily heard a foot and a half from the chest wall without the aid of a stethoscope. In addition, the patient noticed some pain when he was placed on the left side.

The blood pressure was 120/80, the temperature 98°F, the pulse 70, and the respirations 20.

A 7 foot chest plate revealed a small pneumothorax at the left apex, the pleural surfaces were separated at the apex by 1.3 cm. No air was seen in the soft tissues. An electrocardiogram was normal, and other laboratory data were within normal limits.

The patient remained quite comfortable after the first few hours in the hospital. Twelve hours after admission, no unusual cardiac sounds could be made out. He was seen in the Outpatient Department a month after the episode and reported that he had been well.

#### SUMMARY

A brief discussion of spontaneous mediastinal emphysema is accompanied by a short review of pertinent clinical and experimental literature, and 2 cases are reported.

## MEDICAL PROGRESS

### OVULATION

JOHN ROCK, M.D.\*

BROOKLINE, MASSACHUSETTS

UNTIL very recently, medical students were taught that at birth the fetal ovary contained all the primitive follicles that would ever appear, that thenceforth no more eggs would be developed from the germinal epithelium. This view is no longer tenable. Studies of Allen and Creadick<sup>1,2</sup> on the mature mouse and of Evans and Swezy<sup>3</sup> on the rat, guinea pig, dog, cat and man show that from birth to the climacteric, cell division in the germinal epithelium constantly produces new cells, which move centrally into the stroma. In man, these are, before migration, differentiated into ova and follicle cells. This proliferation of germinal cells depends apparently on an intrinsic urge to grow that is characteristic of all living tissue. The primitive follicles, with a similar growth potential, increase in size; and, including those of early embryonic origin, they secrete estrogen, which directs the secondary sex development. Even before birth and continuing until puberty, some follicles enlarge to the appreciable diameter of several millimeters, while estrogen production increases. All the follicles, however, stop short of complete growth. Around each, the theca interna, which is clearly derived from the ovarian stroma, remains rudimentary, and so far as is known, except in very rare and abnormal instances, the nucleus of the ovum does not divide, nor does the ovum escape. During prepubertal life, there is a constant regression of the larger follicles and their ova, as well as a growth of the smaller and younger ones.

With puberty comes a change in the secretion of the pituitary gland which results in a reduction of the rate of ovogenesis.<sup>4,5</sup> Of greater import, however, is the advanced growth that occurs in those ova and follicles already present. Fevold, Hisaw and Leonard<sup>6</sup> have separated the maturity principle from the anterior lobe into a follicle-stimulating hormone and a luteinizing hormone. By action of the former, many follicles increase in size, and the production of estrogen mounts; by action of the latter, the theca interna surrounding the granulosa cells develops into a luteal layer, which contains fat droplets and which

undoubtedly secretes progesterin. When this occurs, the ovum, also in response to these two hormones, possibly assisted by a thyroid secretion, undergoes its first reduction division and extrudes the first polar body.<sup>7</sup> Ordinarily, in the human female, such stimulus from the pituitary gland is sufficient for, or is accepted by, only one of the many ova in both ovaries. As this one ovum matures, its growing follicle, now encased in an active luteinizing theca interna, migrates to the surface of the ovary. Secretion of follicular fluid continues; intrafollicular pressure rises.<sup>8-10</sup> The cortical covering of the follicle suffers pressure ischemia at one point; the theca interna bulges through as a small nipple, and finally the thinned-out wall of the follicle ruptures. The follicular fluid escapes, washing out the cumulus and its contained ovum.<sup>11</sup> Thus, ovulation is accomplished.

With the extrusion of the ovum, and the evulsion of some, if not all, of the granulosa layer, the theca interna closes the ostium and, as some believe, in conjunction with the remaining granulosa tissue, develops rapidly into the new master gland, the corpus luteum. This potent gland of limited life, in addition to estrogen, secretes progesterin, which is chemically somewhat similar to estrogen but pharmacologically quite different from it.

Before the rupture of a chosen follicle is due,—that is, during the preovulatory phase of follicular growth,—many grossly discernible follicles in one or both ovaries contain normal ova surrounded by proliferating granulosa cells. This doubtless indicates that the enclosed ova are also progressing toward maturation. Ordinarily, however, only one apparently forms a polar body and is liberated. After this event, the proportion of degenerating and atretic ova increases.<sup>12,13</sup> Pincus<sup>14</sup> states that in mammals "mature ova retained in the ovary at the time of ovulation ordinarily degenerate." Meiotic division has been reported in a human follicular ovum at a time when a secretory endometrium gave evidence of corpus-luteum activity.<sup>15</sup> This, however, may represent an early step in the breakdown of the egg, since, as Pincus<sup>16</sup> states, "the atresia of ovarian eggs is often initiated by the formation of a maturation spindle."

All articles in this series will be published in book form: the current volume is *Medical Progress: Annual, 1940* (Springfield, Illinois: Charles C Thomas Company, 1941. \$4.00).

\*Research associate in obstetrics and instructor in gynecology, Harvard Medical School; visiting surgeon, Free Hospital for Women.

Ova that do grow following ovulation regress before the maturation stimulus from the pituitary comes again after menstruation.

It is clinically very significant that during the activity of the luteal tissue, which begins shortly before ovulation,<sup>17</sup> no further normal maturation of other ova takes place. When the corpus luteum regresses and progesterin diminishes, a new crop of partially developed ova and follicles begins advancing toward maturity.

To clarify some later considerations, it is well to review the physiology of menstruation. Estrogen from the follicles stimulates the endometrium to grow—to proliferate. The stroma becomes thicker; the arterioles increase in size, and the capillaries in complexity; the glands become larger and more numerous. The histologic picture of both the glands and the stroma is well known and characteristic.<sup>18-20</sup> At the time in the menstrual cycle when progesterin, elaborated by the corpus luteum, becomes effective, the proliferated endometrium is said to become "secretory": it "functions." This secreting or functioning mucosa likewise has a histologic appearance that, conversely, specifically indicates progesterin activity. The human corpus luteum ordinarily functions only just before and for two weeks after ovulation. Enough progesterin to elicit the cytologic picture of beginning secretion in the endometrium is usually produced during about the second twenty-four hours after ovulation. The cytology of this continuing functional phase exhibits a well-known orderly and progressive series of stages each of which individually possesses distinguishing features. Thus, by examination of a biopsy specimen and recognition of any one of the stages, the observer may estimate how long progesterin has been acting, and therefore how long the corpus luteum has been present. And so, by the endometrium, one may estimate when ovulation took place.

If conception and implantation have not occurred, the activity of the corpus luteum finally ceases, and the potentiality to bleed, which has been developed in the endometrium by estrogen and kept from expression by progesterin, is released by withdrawal of the progesterin.<sup>21</sup> As a result, blood is extravasated into the tissue. This disintegrates and menstruation ensues.<sup>22</sup>

#### TESTS FOR OVULATION

Are there any means, besides endometrial biopsy, by which one can tell whether and when ovulation, that event of such potentially tremendous import to the individual and to society, takes

place? Of the numerous tests that have been proposed, the following are the most popular ones.

#### Mittelschmerz

Some women experience with ovulation a momentary lancinating pain in either lower quadrant, usually superimposed on preceding dull discomfort of several hours or even days. Wharton and Henriksen<sup>23</sup> state that the pain is usually so mild as to be undetectable until after educated attention has been directed to it. Ito<sup>24</sup> reported that 70 per cent of a group of female medical students and physicians were able to detect ovulation by their subjective symptoms, whereas only 40 per cent of nurses in the series studied were able to do so.

In Boston, surely not more than 15 per cent of women receive such information. This discrepancy is presumably not due to territorial favoritism on the part of Nature, but may indicate a lack of particular education and attentiveness. Doubtless, many hitherto heedless women could be trained. Although the information is very useful, distressful confusion might arise in many emotional females from intensively applied abdominal introspection. However, the method has merit and should be more commonly applied.

#### Intermenstrual Bleeding

In 20 per cent of the cases studied by Wharton and Henriksen,<sup>23</sup> the *Mittelschmerz* was accompanied by intermenstrual bleeding profuse enough to require protection. More commonly, bleeding at the midcycle arises unassociated with pain. The flow varies considerably in amount. Sometimes, it appears merely as a pink or brownish stain in mucus. In his study of intermenstrual bleeding in macaques, Hartman<sup>25</sup> found that, when bleeding occurred at ovulation time, it was usually in microscopic amounts. Wharton and Henriksen microscopically examined the vaginal washings of 5 women with no gross bleeding and found blood in all. Papanicolaou<sup>26</sup> also noted that almost 24 per cent of vaginal smears taken on the fourteenth day contained microscopic traces of blood. This flow at ovulation time is sufficiently gross to attract the attention of probably less than 5 per cent of women.

#### Biochemical Study

In many laboratories, efforts are being made to measure in blood and in urine the amounts of female sex hormone—the combined estrogens. When the values obtained for estrogen content of urine for several unit periods of twenty-four or forty-eight hours throughout the cycle are plotted

against time, curves are obtained that are considered typical of the ovulatory cycle. Although the absolute amounts of total estrogen in the urine may vary in assays by different chemists, there is a semblance of uniformity in the curves. Those of Gustavson et al.<sup>27</sup> do not reflect the findings of Smith and Smith<sup>28</sup> that a marked peak is demonstrable twelve or thirteen days before the next catamenia, but their published curves do show peaks between the fourth and twenty-first days before menstruation. Werner<sup>29</sup> also comments on the appearance of an estrogen peak at about the middle of the cycle, and its reduplication a few days later. Furthermore, Gustavson states that in every case the estrin excretion falls to zero at or very shortly preceding the next ensuing menstrual period.

Kurzrok, Kirkman and Creelman<sup>30</sup> reported the sudden appearance of the follicle-stimulating hormone (prolan A) in the urine, usually about the middle of the menstrual cycle. Using a more sensitive method, D'Amour<sup>31</sup> and Werner<sup>29</sup> obtained values for urinary gonadotropin throughout the cycle. In the majority of their cases, the resulting curves showed a peak about sixteen to twelve days before the succeeding menstruation.

Another biochemical measurement—that of the excretion in the urine of pregnanediol, a breakdown product of progesterin—is also informative.<sup>32</sup> When pregnanediol first appears during the cycle, one may assume that the corpus luteum is in the ascendancy, since, in the absence of conception, progesterin (containing progesterone) comes only from the corpus luteum.

Collection and delivery of many specimens of urine or blood entail much inconvenience, and the chemical analysis requires much time and expense, as well as a rare degree of skill. The determination of hormone content is therefore still to be considered a research method, and is of relatively little value for the clinical problem of detecting ovulation.

### *Basal Body Temperature*

Rubenstein<sup>33</sup> proposes that, in normal women during the childbearing period, rectal temperatures taken at the same time each day and under standard basal conditions vary characteristically during the menstrual cycle, and if plotted against time describe a specific curve informative of ovulation. His proof that the selected portion of the curve truly denotes ovulation depends to some extent on a few pregnancies that have followed coitus at this time but, more especially, on a change in the quality of epithelial cells recovered from the depths of the vagina. This change he

sees occurring synchronously with what he considers to be characteristic variations in temperature. It would seem easy for patients to read and record their rectal temperatures at the same hour every day, but I must confess my inability to recognize in more than one of the few curves obtained from my patients the particular series of variations of from less than 0.5 to 1°F. or slightly more that are taken to indicate ovulation. Since the accuracy with which patients can determine and record rectal temperatures at particular times under particular conditions is questionable, and especially because variations of so slight a degree are incident to so many conditions besides ovulation, this method does not appear to be a reliable one for determining the time of ovulation.

### *Vaginal Smears*

In 1917, Stockard and Papanicolaou<sup>34</sup> presented their pioneer work relating changes in the vaginal epithelium of guinea pigs to the estrous cycle. On this groundwork, a very large part of modern sex endocrinology has been built. In 1933, Papanicolaou<sup>26</sup> described a method of obtaining the vaginal desquamate of women and of staining a spread of the cells. He designated the varying qualities of the stained smear as indicative of definite sequential phases in the ovulatory cycle of the human female. Many ardent workers have used his method and learned much about the effect of estrogen on the vaginal epithelium. From smears, one can usually detect the failure of the ovaries to form many active follicles, as in some cases of amenorrhea and in the menopause, and likewise discover the presence of many follicles secreting estrogen in the ovulating woman. In smears, one also detects the effect of the relatively enormous amount of estrogen secreted by the placenta in pregnancy. Few, however, and I am not one of them, have been able, with Papanicolaou's stain, to see changes specifically indicative of ovulation on or about the day it occurs. Hence, as a method of detecting ovulation, the vaginal smear is yet of very limited, if any, clinical value. Great conservatism in its use is also advised by other investigators.<sup>35, 36</sup>

A new method of staining vaginal smears recently described by Shorr<sup>37</sup> may prove helpful. By its use, one can demonstrate ovulatory changes in the macaque.<sup>38</sup> In the macaque, however, ovulation is associated with exceedingly gross alterations in the tissues of the vagina and vulva, which are only very faintly simulated in the human female. It seems to me that variations in the vaginal desquamates during the human cycle are equally slight.

### Biopotentials

In 1935, Burr and his collaborators<sup>39</sup> reported that, with ovulation in the rabbit, there was a demonstrable increase in the difference in potential between two electrodes, one placed above the symphysis and the other in the vagina. Reboul, Friedgood and Davis<sup>40</sup> repeated Burr's experiment and furthermore discovered by direct observation that this change in biopotentials was synchronous with ovulation. In 1937, Burr and his associates<sup>41</sup> reported a similar phenomenon in one woman. This was also demonstrated in one case in my clinic.<sup>42</sup> Rock, Reboul and Snodgrass<sup>43</sup> later reported changes in difference of potential at the time of ovulation in 9 other women, but because 3 of these were found at operation to be only on the verge of ovulation, it was proposed that the recorded increase in the difference of potential was merely associated in some way with ovulation. This conservatism was supported by Rogers's<sup>41</sup> observation that a similar change in biopotentials was obtained in the spayed rat during the last day of estrogen-induced estrus. However, in 1940, Barton<sup>45</sup> suggested that wide changes in the difference of potentials between two index fingers indicated ovulation. Furthermore, she concluded from her data that ovulation might occur at any time during the cycle, and sometimes twice in the same cycle. Impressed by the facts that the abdominovaginal sign was obtained sometimes before and sometimes with or after ovulation, that its polarity was inconstant and, particularly, that there were wide variations in the magnitude and duration of the change in difference of potential, Snodgrass<sup>46</sup> attempted to discover something more about the cause of these potentials. Very significantly, he found that the potentials between fingers were affected proportionately by changes in the environmental temperature of one finger. It was also noted that daily differences in potentials between fingers were very probably influenced by atmospheric temperature and humidity affecting the body as a whole.<sup>46, 47</sup> Finally, of great clinical value is the fact that, contrary to Barton's findings, rather intensive study in my clinic proves that the so-called "finger-to-finger potentials" have no relation whatever to ovulation. As the complete report of our researches has not yet been published,<sup>48</sup> I take this opportunity to say that, like basal body temperatures and vaginal smears, biopotentials may be affected by ovulation but not in such a critically peculiar way as to indicate ovulation, and therefore, like the other methods, cannot be used clinically to detect this significant event.

### Endometrial Biopsy

Is there any dependable means of telling whether or not ovulation takes place? I referred above to the fact that estrogen alone causes a proliferation of the endometrium that results in a characteristic cytologic appearance, and that, when progesterin comes into action, function or secretion is evoked in the proliferated tissue, again with a typical cell picture in the glands and later in the stroma. By aspiration into a small suction curet of a fragment of endometrium before an expected catamenia, one may, after section and staining, determine whether or not progesterin has been elaborated in the ovary.<sup>20, 49, 50</sup> If the signs are there, one may deduce the presence of a corpus luteum, and hence that ovulation has taken place. At present, endometrial biopsy is the best clinical test for the occurrence of ovulation.

### TIME OF OVULATION

So regular are the successive changes in the functioning endometrium as the secretion of progesterin waxes with the growth of the corpus luteum and wanes with its regression, that one may discover not only *if* ovulation occurs but also approximately *when* it occurs.

In the first years of this century, the prevailing view among biologists was that the egg was released about the time of menstruation.<sup>51-53</sup> Recently, Barton<sup>15</sup> deduced from observations of finger-to-finger potentials, which I consider not at all indicative of ovulation, that in 18 per cent of them (24 per cent in a smaller series<sup>64</sup>), it occurred in the midcycle, but in the rest at any time in the cycle, even during menstruation. Rubenstein<sup>33</sup> believes that he has demonstrated by changes in basal body temperatures and vaginal smears, both of which I consider misleading or uninformative, that ovulation usually takes place near the midcycle, but may occur at other times, even during the menses. By correlation of observations of the ovaries at laparotomy with the anticipated dates of catamenia, Ogino,<sup>55</sup> on the other hand, convinced himself that ovulation occurs between the sixteenth and twelfth days before menstruation; and Knaus,<sup>56</sup> by observation of the myometrial response to posterior pituitary extract as affected by progesterin, concluded that it takes place on the fifteenth day preceding the onset of the menses. By correlation of the age of the corpus luteum (as evidenced in the stage of endometrial functioning detected by biopsy) with the date of the subsequent menstruation, in more than 400 biopsies in my clinic, we have, in about 75 per cent of these, placed maturation of the ovum

and probable ovulation at the sixteenth to the twelfth day before the onset of menstruation. At present, by more accurate reading of the endometrial section, in about 90 per cent of cases it is possible to foretell within about two days when, in the absence of pregnancy, menstruation will occur. The calculations are based on the assumption that the corpus luteum functions for about two weeks, and the accuracy of prophecy bespeaks the soundness of the theory. In the few remaining cases, the question may well arise whether or not something is wrong with the hormonal control of endometrial bleeding, rather than whether or not ovulation takes place at the time indicated by the degree of progestin effect.

By applying this proposition to the prevention of pregnancy, we believe we have proved, as many others have, that ovulation normally occurs about fourteen days before the succeeding menstruation. Allowing three days for the effectiveness of spermatozoa and an admittedly long period of three days for the susceptibility of the egg to fertilization, we have reduced the fertility rate among 109 women from 90 pregnancies per 100 person-exposure years to only 4.<sup>57</sup> The proposition that the ovum is freed on about the fourteenth day before menstruation cannot be far wrong when coitus is freely practiced at other times by 109 very fertile women and so very few of them become pregnant. The exceptions are properly explained by the impossibility of always accurately placing the next menstruation.

It should be noted that I do not say that ovulation occurs about the fourteenth day of the cycle. From our biopsy studies, we are convinced that in cycles varying in length from the ordinary twenty-seven days, that is, in cycles that terminate with menstruation on the twenty-eighth day, the variable is in the follicular (proliferative) phase — the period following catamenia. The luteal or secretory phase is relatively constant, varying from 12 to 16 days. On the basis of controlled mating experiments in the chimpanzee, Elder<sup>58</sup> in like manner emphasized the importance of taking into account the length of the cycle when estimating ovulation time: that is, he found ovulation to take place earlier in short cycles than in long ones.

#### FAILURE OF OVULATION

Since long before the suggestion in 1908 by Hitschmann and Adler<sup>59</sup> that the ovary might have a causal relation to cyclic changes in the endometrium, the occurrence of uterine flow has been regarded as a sign that ovulation had taken place, and amenorrhea has been considered evidence of its failure. It is now known that neither of

these views is strictly tenable. In only 1 among more than 400 biopsies, have I seen evidence of a corpus luteum, bespeaking ovulation, in a patient who did not, in the absence of pregnancy, subsequently menstruate. Such a rarity offers only a dangerous clinical pitfall. A diagnosis of ovulation during amenorrhea must never be made without clear proof.

Likewise, in about 10 per cent of 392 infertile women, we<sup>60</sup> found evidence of anovulatory menstruation. In 50 per cent of this group of anovulatory patients (or about 5 per cent of the entire group of sterile women studied), such evidence was obtained by more than one biopsy—that is, flow from an endometrium still in the proliferative stage. This phase, as I have pointed out, indicates the presence in the ovaries only of active follicles and not of a functioning corpus luteum. The absence of this gland accounts for the fact that anovulatory menstruation occurs at widely varying intervals and not with the usually constant periodicity of the flow that follows the action and regression of a corpus luteum. Not only do normal postovulatory menstrual periods commonly recur at fairly constant intervals, but such catamenia are similar in the duration, quantity and quality of flow. On the contrary, the flowing that occurs with failure to ovulate is very variable in these details. For this reason, I think the term "aperiodomenorrhea," meaning irregular, immeasurable menstruation, is proper. I have no accurate figures, but I should guess that, in women between sixteen and forty-five years of age, failure of ovulation is reflected in aperiodomenorrhea at least three times as often as it is in amenorrhea. The latter, like the symptomatic syndrome of the menopause, usually indicates the failure not only of ovulation but also of appreciable growth of all but perhaps a very few follicles.

#### INDUCTION OF OVULATION

The means to stimulate ovulation should logically have reference to the normal physiologic activators of ovular and follicular maturation. Since comparatively little is known of the physiology of human ovulation, it is not surprising that efforts to evoke this phenomenon in women who suffer its failure are often in vain. Even when ovulation does follow certain procedures, one is usually unable accurately to determine the successful underlying process.

#### *Thyroid Therapy*

Results from thyroid medication are a good example of inexplicable consequent ovulation. In a small proportion of cases (perhaps not more than

5 per cent), ovulation follows the administration of as little as 1 gr. of the dried gland daily, even in patients whose basal metabolic rates are normal. Pincus<sup>61</sup> states that the thyroid may promote oogenesis to a certain extent. Salter<sup>62</sup> cites evidence indicating that the thyroid gland is related to ova production in the bird.

### *Diet and Hygiene*

Empirically, likewise, the relief is called for of anemia and the probably associated occult deficiencies of vitamins or minerals when ovulation fails, whether or not to the extent of amenorrhea. This should be the first attack on the problem. Although the condition is not so serious as the subclinical pellagra considered by Mc Lester,<sup>63</sup> one should remember his advice that "the physician who would treat deficiency diseases cannot afford to be timid." It is therefore well to give relatively large doses, especially of the vitamins, when one is working on the theory that they may be missing. Physical and mental hygiene should not be neglected. Exercise, rest and equanimity are beneficial. Although the relation between emotional tone and ovarian function is not clearly understood, it is frequently apparent, and an effort should be made to resolve what mental conflicts one can discover.

### *Hormones*

During the last few years, endocrinologic attacks on anovulation in the human female have been suggested by attempts on laboratory animals that were relatively successful.

**Chorion hormone** Experiments were undertaken with the chorion or anterior pituitary like hormone, extracted from the urine of pregnancy. This evokes maturation and ovulation in even the immature rat and mouse, and so surely elicits these phenomena in the isolated rabbit doe as to establish the dependable Friedman test for human pregnancy. This hormone, however, under any of its many pharmaceutical titles, completely fails to produce the desired result in human patients. Geist and his co-workers,<sup>64</sup> Hamblen<sup>65</sup> and others agree that it is useless for this purpose in the clinic. Hartman<sup>67</sup> likewise found it to yield "far from promising" results when tested on the laboratory primate, the macaque monkey.

**Pituitary extract** Trials were also made with extracts of the anterior lobe of the pituitary gland of sheep. Zondek and Aschheim<sup>68</sup> and Smith and Engle<sup>69</sup> originally demonstrated the dependence of follicular maturation on the anterior hypophysis. Pincus<sup>70</sup> marshals much laboratory data on

the rabbit to show that this gland materially influences the ripening of ovum and follicle. Unreported trials with a commercial preparation of this material in my clinic failed utterly to accomplish anything among a group of anovulatory patients. Research is now in progress with an improved extract from sheep's anterior hypophysis, which is giving encouraging results, but only in follicular growth and in the production of uterine bleeding.

**Serum gonadotrope** Recently, there came to hand the potent follicle stimulating hormone from the serum of pregnant mares. Davis and Koff,<sup>71</sup> Siegler and Fein<sup>72</sup> and Hall<sup>73</sup> had reported great success with it. Although we<sup>74</sup> tried many different dosages and sequences in 48 patients, our results convinced us that this hormone, too, was quite unsatisfactory as a maturing hormone for human follicles. The recent report of Geist and his associates<sup>69</sup> substantiates our findings.

**Chorion hormone and serum gonadotrope** Hissaw, Greep and Fevold<sup>75</sup> showed that a critical proportion of follicle stimulating and luteinizing hormones made juvenile female monkeys ovulate. Since the chorion hormone is predominantly luteinizing, and the serum gonadotrope is in laboratory animals almost always only follicle stimulating, it was hoped that a combination of the two in sequence or combined in various proportions would produce the desired result. Among 22 anovulatory patients given these hormones in different doses, combinations and sequences, not one gave evidence of ovulation.<sup>74</sup> Hamblen<sup>68</sup> reports greater success with such combined and cyclic forms of therapy. I still believe, on the basis of laboratory studies on animals, that a particular combination and sequence of chorion hormone and serum gonadotrope may prove satisfactory. A better way would be to regulate the patient's own glandular system, if one only knew how.

**Estrogen** Zondek<sup>76</sup> and others have shown in animals that small doses of estrogen are stimulating to the anterior hypophysis, which responds by increasing its maturation influence on the follicle. Greep's<sup>77</sup> preservation of the corpora lutea of pregnancy, by injection of estrogen in rabbits from which both the hypophysis and the uterus had been removed, suggests that the mediation of the hypophysis is not always necessary.

Similarly, in human beings, repeated small doses of estrogen occasionally seem to exert a stimulating effect on the ovaries. Larger doses inhibit the pituitary gland, and if given daily for three or four weeks, commonly prevent ovulation in the regularly ovulating woman. Estrogen, then, is a

means not to be depended on, but one that apparently causes no permanent damage and in small doses may occasionally support follicular growth. Better results from pituitary gonadotrope may be obtained if small doses of estrogen are given simultaneously. The dosage must be nicely adjusted to the individual patient, for surely estrogen inhibits follicular growth if given in large quantities.<sup>78</sup>

### X-Ray

In 1935, Mazer and Spitz,<sup>79</sup> in a report of their own work, gave utterance to the scattered experiences of many other clinicians by stating that so-called "stimulating doses" of x-ray would bring about ovulation in approximately 50 per cent of patients with amenorrhea, and would regulate (possibly by establishing ovulation) the menstrual flow of women suffering from aperiodomenorrhea—dysfunctional uterine bleeding. These results were confirmed in a later series of cases by Mazer and Baer.<sup>80</sup> Rutherford<sup>81</sup> analyzed the cases treated in my clinic, and likewise showed that ovulation occurred in about 54 per cent of the anovulatory patients whose ovaries were exposed to 50 or 60 r three or four times at weekly intervals. This treatment, I believe, should be kept as a last resort. The x-ray is not stimulating; it is destructive. It causes atresia of follicles from the more advanced to the youngest, according to the degree of exposure. The subsequent ovulation in the favorable cases is commonly attributed to the removal of a follicular influence that inhibited the pituitary gland. In some of the unfavorable cases, it may merely fail to do this, but it possibly also has a deteriorating effect on the growth impulse of the germinal epithelium, which thereafter may fail to produce any new oocytes, or to produce normal ones that can mature. From the uniform results of geneticists,<sup>82, 83</sup> one may be sure that even though ovulation is effected, the genes of the entire germinal epithelium thus exposed are changed; and one may well fear for the results in progeny when two germ cells, both descended from irradiated epithelium, are combined in the third or fourth generation. This may not seem an imminent consideration, but I now believe it should be one, and that x-ray treatment, although an attractive escape from a therapeutic morass, should therefore be avoided if possible.

\* \* \*

It will be seen from the foregoing that I consider the hormonal treatment of anovulation to be definitely in a barely encouraging experimental stage. The first attack should be by copious use

of hygienic and dietary measures, supplemented by small doses of thyroid and very small doses of estrogen. An improved pituitary extract may be forthcoming. If available, this should be added to the other measures, alone or in conjunction with chorion hormone, in nicely timed injections. X-ray therapy should serve as a last resource. My observation of the stubborn anovulators, especially of the amenorrheic type, leads me to believe that more careful attention to diet and hygiene during the pediatric years might prevent much gynecologic difficulty. Studies directed to the frequency of ovarian dysfunction in antecedents and relatives of patients exhibiting this derangement might also prove helpful, by establishing an inheritable factor.<sup>84</sup>

## CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED  
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

### CASE 27491

#### PRESENTATION OF CASE

A sixty-three-year-old locomotive engineer was admitted to the hospital because of painful and difficult urination, and aching and swelling in the right forearm.

Two years before entry, the patient began to have nocturia. After a year, the stream became small and difficult to start, and urination was quite painful. A local physician catheterized the patient periodically thereafter, and told him that he had "chronic inflammation" of the urethra and an "enlarged" prostate. Four months before entry, he began to have a steady ache in the right wrist. He noticed that when he was at work in his locomotive the ache was worse when he rested his right forearm "flat" than when he rested it on its ulnar surface. Two weeks before entry, the right wrist began to swell.

The patient's mother had died of "cancer of the liver." As a youth, he had a "soft chancre" and a bubo in his groin. About forty years before entry, he suffered a severe burn of his right leg. On two subsequent occasions, he fractured this leg. He dislocated his left wrist once and his right wrist twice, the last accident occurring ten years before entry. He had always had a very dry, easily chapped skin. He had had a chronic morning cough, with small amounts of sputum, for fifteen years before entry.

He had been seen in the hospital fourteen years prior to the present admission, because of tremor, dyspnea and palpitation of a year's duration. The thyroid gland was enlarged and firm. The basal metabolic rate was + 40 per cent. Auricular fibrillation was present, and responded to quinidine therapy. A subtotal thyroidectomy was performed (pathological diagnosis: hyperplasia), and the patient discharged improved.

On the present admission, examination showed an obese, apparently healthy man, with unremarkable heart, lungs and abdomen. The prostate gland was very small and of fibrous consistence, without palpable nodules. There was a firm swelling in the region of the head of the right radius, with redness of the overlying skin and local heat. The skin, as a whole, was dry and scaly.

The temperature, pulse and respirations were normal; the blood pressure was 140 systolic, 85 diastolic.

Examination of the blood showed a white-cell count of 9400 with 67 per cent polymorphonuclears, and a red-cell count of 4,280,000 with 13 gm. hemoglobin. The blood Hinton reaction was negative. The blood calcium was 9.3 mg., and the phosphorus 3.1 mg. per 100 cc.; the phosphatase was 3.5 Bodansky units. The nonprotein nitrogen was 12 mg. per 100 cc., and the urine showed a + test for albumin.

A roentgenogram of the right wrist showed a number of areas of destruction in the distal extremity of the radius, with some periosteal formation of new bone on the margins of the adjoining part of the shaft. Very little atrophy was present. Both medulla and cortex were involved, and there was definite soft-tissue swelling posterior to the involved joint. Roentgenograms of the pelvis and the chest were negative.

On the ninth hospital day, an operation was performed.

#### DIFFERENTIAL DIAGNOSIS

DR. GRANTLEY W. TAYLOR: This is a confusing story, and I think we are not going to get far with it until we see the x-ray films. Then it is going to be a matter of guessing the diagnosis. May we see the x-ray films first?

DR. JAMES R. LINGLEY: This is the area of destruction, rather a lobular area, in the lower extremity of the radius. In the lateral view, one can see destruction of the cortex posteriorly and definite thickening and edema of the soft tissues.

DR. TAYLOR: Somewhere in this interpretation, it speaks of the involved joint. That is just a loose method of expression, I take it. You do not see anything in the films to show that there is an involved joint?

DR. LINGLEY: No.

DR. TAYLOR: On reading the history, I became progressively more confused and gave thought to a number of things that I might have to consider when I saw the pictures. The patient dislocated his wrists some time before admission. I do not know what happened, but such dislocations are extraordinarily rare. I wondered if he had old traumatic arthritis, with absorption and new-bone formation around the joint, especially because of the allusion to the joint in the interpretation. Very much against that diagnosis are the facts that no atrophy was observed by x-ray study, and that motions were carried out with apparently adequate range. Then, I considered the question whether he had punched-out areas

in the bone near the joint, due to gout. There was nothing in the history either for or against it. The question of infection arose very strongly in my mind, because of the urologic difficulties—chronic urethral discharge, painful urination and a history of a soft chancre and bubo; it seemed to me that we might reasonably consider the possibility of gonorrheal arthritis in this case.

Syphilis of the bone, Charcot joint or gumma, it seems to me, reasonably enters into the possible diagnosis. However, the negative blood Hinton reaction, the fact that this lesion was painful and the fact that it was not in a weight-bearing joint all argue against anything like a Charcot lesion.

Tuberculosis of the bone is very unusual at this age, but it may occur, especially in the vicinity of a joint. Pyogenic osteomyelitis is also a very reasonable possibility. Against it are the normal chart, the normal white-cell count and the lack of a preponderance of polymorphonuclears in the differential count.

Then we move on to the consideration of neoplastic diseases of the bone. The patient was in an age group in which such diseases as Ewing's tumor and osteogenic sarcoma are rare. The latter occurs in this age group almost exclusively in association with very extensive Paget's disease of the bone, of which we have no evidence. The reticulum-cell-sarcoma type of lymphoma, which has recently been established as a clinical entity, is a rather capricious disease in the sense that we have not seen enough cases to say what its usual habits are, or what clearly defined characteristics it has on clinical observation or x-ray examination. It is something that must be considered and is hard to rule out. Hodgkin's disease of the bone, almost invariably associated with Hodgkin's disease elsewhere, also gives a confusing x-ray appearance and is sometimes very difficult to identify. A single plasma-cell myeloma should definitely be considered. I believe it is very unusual in a location of this sort. No mention is made of the serum protein or the possibility of Bence-Jones protein in the urine, or any of the other characteristics on which that diagnosis could reasonably be based.

Finally, we come to metastatic neoplasms. Metastases are very unusual below the elbows and knees, but they may occur. If we consider the diagnosis of metastases, we must find a primary focus of disease. We have no evidence of a primary focus anywhere. The concomitant problem this patient presents is urinary-tract difficulty. The small prostate, one that is not nodular, does not suggest a neoplasm. The negative spine and pelvis

plates practically rule out the possibility of metastases.

To all these possibilities, there are good objections, but it seems to me that we must at least have "got warm" somewhere in this rehearsal of the list of diseases. I should think that the objections to pyogenic osteomyelitis are less convincing than those for most of the other conditions. We have seen a number of cases of pyogenic osteomyelitis in which there was no elevation of temperature and in which there was no particular change in the leukocyte count, which is unusual. Let us consider that diagnosis in the light of the x-ray findings. We have surprisingly little new-bone formation. It is described in the notes, but is not a conspicuous feature in the study of these x-ray films. We do have rarefaction in the bone, but without surrounding condensation of bone, which is commonly seen around the Brodie's abscess type of chronic, indolent bone infection. In favor of pyogenic osteomyelitis are soft-tissue swelling, which is not definitely a tumor, and edema of the tissues, which is less commonly found in conjunction with neoplasm than with inflammatory conditions. It seems to me that pyogenic osteomyelitis is the most probable diagnosis. I should definitely entertain, in the background, however, the possibility of primary malignant neoplasm.

Dr. Lingley can probably contribute to this discussion by further comment on the x-ray films, considering the diagnostic problem that they present; the diagnosis in this case is almost entirely a problem for the roentgenologist and pathologist.

DR. LINGLEY: As Dr. Taylor has remarked, the presence of edema of the soft tissues is an important finding in ruling out a tumor in this case. We very rarely see either a malignant or a benign tumor with such definite edema as we have in this case. I think that the presence of edema immediately puts the lesion in the infection group. The question now comes up whether it is pyogenic infection, syphilis or tuberculosis. I think the roentgenologic appearance fits very beautifully a pyogenic infection. There is destruction, with some periosteal new-bone formation. Tuberculosis is almost always entirely destructive. There can be new-bone formation in tuberculosis, but in this case there is more than one would expect if it were tuberculous. Syphilis is a definite possibility. The type of periosteal reaction in this case could be classed as the lacelike type of periosteal bone formation that one sees in syphilis. I should place pyogenic osteomyelitis as the first diagnosis, and syphilis as the second.

DR. ALLEN G. BRAILEY: Is the fact that the phosphatase level was normal of any help?

DR. TAYLOR: I should think not. Dr. Franseen has studied these reactions. A high phosphatase level is evidence of osteoblastic activity. We may see a very high one in diseases like Paget's disease, and with some of the osteogenic sarcomas. On the other hand, it may be fairly low in cases of bone sarcoma, especially when there is not a great deal of osteoblastic activity. The low figure in this case might be taken as evidence against osteogenic sarcoma, but I do not believe that it would be indisputable evidence. Some of our osteomyelitis cases have had high phosphatase levels.

DR. CLIFFORD C. FRANSEEN: I agree entirely. The normal phosphatase and the absence of evidence of new-bone formation fit together. That is all one can say.

#### CLINICAL DIAGNOSIS

Osteomyelitis?  
Lymphoma?

#### DR. TAYLOR'S DIAGNOSIS

Pyogenic osteomyelitis.

#### ANATOMICAL DIAGNOSIS

Chronic osteomyelitis of radius (*Staphylococcus aureus*).

#### PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: This patient was operated on, and when the cortex was incised a free flow of pus was obtained. The material curetted from the cavity showed chronic inflammation and no evidence of neoplasm. Cultures of the pus showed *Staphylococcus aureus*.

A PHYSICIAN: What about the urinary tract?

DR. MALLORY: I know nothing more about that. The patient is still convalescing.

#### CASE 27492

#### PRESENTATION OF CASE

A seventeen-year-old Portuguese-American student was admitted to the hospital because of swelling of the left leg.

The patient was well until about six months before entry, when he noticed painful swelling of his right shin. He thought that he had struck the shin against hard objects on several occasions. The swelling gradually increased. After a few months, a local physician was consulted. After a roentgenogram of the leg was taken, a biopsy was requested and refused. Several months later, the patient came to the hospital.

On admission, the patient appeared healthy; the heart, lungs and abdomen were normal. There was a diffuse, bony hard, fusiform swelling on the posteromedial aspect of the left tibia, involving the middle third of the shaft, continuous with the normal portions of the shaft at its margins.

The temperature, pulse and respirations were normal; the blood pressure was 120 systolic, 70 diastolic.

Examination of the blood showed a white-cell count of 13,200 with 74 per cent polymorphonuclears, and a red-cell count of 5,070,000 with 85 per cent hemoglobin. The blood calcium was 11.6 mg. and the phosphorus 3.8 mg. per 100 cc., and the phosphatase was 6.3 Bodansky units. The blood Hinton reaction was negative. The urine was normal. A tuberculin test was negative in a 1:10,000 dilution.

A roentgenogram of the left leg showed a fusiform thickening of the tibia, at the junction of the upper and middle thirds. The periosteum in this area was markedly thickened, and in one or two places there was slight roughening of the periosteum, with some destruction. There was very slight soft-tissue thickening, superimposed. A cavity, measuring 1 by 1.5 cm., situated at the base of the region of periosteal formation of new bone, was visible only on a film that had been much overexposed.

On the seventh hospital day, an operation was performed.

#### DIFFERENTIAL DIAGNOSIS

DR. THOMAS ANGLEM: May we see the x-ray films?

DR. JAMES R. LINGLEY: Here we see the area of fusiform thickening described, which is due mainly to the gross thickening of the cortex on the posterior margin of the shaft. In the overexposed film, there is one small linear area of rarefaction about 1.5 cm. in length within the area of new-bone formation, but I cannot demonstrate it with this light. There is no surrounding soft-tissue mass, and no edema of the soft tissues.

DR. ANGLEM: There is very little in this story that is of any diagnostic aid. It seems to me, as in the last case, that the diagnosis rests on the interpretation of the x-ray films. The essential finding in the history is a story of progressive swelling of the tibia for six months, associated with some pain. At the time of examination, the boy was apparently still in good general health, with normal temperature, moderate leukocytosis—13,200—and a slight elevation in the serum-phosphatase level; otherwise, the findings were essentially negative. We get some assistance from

consideration of certain negative findings. The tuberculin test was negative in a 1:10,000 dilution. This, coupled with the x-ray picture, which has none of the usual characteristics of a tuberculous bone lesion, I think, permits us to rule out tuberculosis. The blood Hinton reaction was negative; however, this lesion conceivably could be syphilitic on the basis of its x-ray appearance. It shows a degree of condensation in the cortical bone consistent, I think, with syphilitic osteitis, and the area of destruction might also be explainable on the basis of a syphilitic lesion. However, it would be very hazardous to make a diagnosis of bone syphilis in the presence of a negative blood Hinton reaction. I believe that we can disregard syphilis as a possibility.

The diagnosis comes down to a choice between a low-grade infectious process of bone and malignant tumor. Of the malignant tumors, I think only two need be considered seriously—endothelioma of bone and osteogenic sarcoma. The position of this lesion is typical of what we usually see in Ewing's sarcoma, but the other features of the disease are lacking. It is unusual to see this degree of sclerosis or condensation of bone in Ewing's tumor, and the sharply localized small area of destruction is not the usual picture. We can rule out Ewing's sarcoma.

Osteogenic sarcoma usually occurs in the metaphysis and is relatively uncommon in the mid-shaft of the bone. Nevertheless I think that it must be considered a possibility. On the whole, this picture does not seem to me to be the picture of osteogenic sarcoma. The usual classic features of the disease are lacking. There is no reactive triangle that I can make out. The small area of destruction seems to be sharply localized, and the area of reactive bone is much more diffuse and spreads around the entire circumference of the bone rather than being limited to the area in which the destruction is apparent.

A low-grade infection of the bone seems the most likely possibility here. As in osteogenic sarcoma, it also occurs most commonly in the metaphysis rather than in the shaft, but in contrast with the usual form of acute hematogenous osteomyelitis, which occurs predominantly in the very young, the subacute and chronic forms occur very frequently in the shaft and are relatively common in older children and young adults, the age group in which this patient falls. The absence of any definite soft-tissue swelling and the absence of tumor are against infection. Nevertheless, in any extremely low-grade process existing for a long time, it is possible to have infection without any superimposed soft-tissue swelling or edema. The

sharply localized punched-out area in the cortex seems to me to suggest, from the x-ray appearance, a cortical abscess more than an area of destruction from a malignant tumor, and the periosteal reaction in the surrounding bone is consistent with a low-grade infectious process. I should say that the first and most likely possibility in this case is low-grade infection, —osteomyelitis,—with osteogenic sarcoma as a definite possibility.

DR. TRACY B. MALLORY: Dr. Lingley, do you want to discuss the radiologic aspects further?

DR. LINGLEY: I agree with Dr. Anglem in his diagnosis. I think the picture is very characteristic of Garré's<sup>1</sup> sclerosing osteomyelitis. It is a low-grade infection that has been present for a long time, producing dense, well-organized new bone. The character of the new bone is very much against any type of tumor. Ewing's sarcoma is the most likely tumor in a location involving a large area of the shaft, but there is no onion-peel formation and not enough destruction, and the new bone is too dense and well organized.

DR. GRANTLEY W. TAYLOR: In one x-ray film, there is a suggestion that there has been distortion of the weight-bearing line of the tibia. If that is a correct interpretation, it seems to me that it is a finding we have observed in a number of cases of osteomyelitis in the shaft of the bone: definite overgrowth on one side, with a slight distortion of the axis of the bone.

#### CLINICAL DIAGNOSIS

Osteoid osteoma.

DR. ANGLEM'S DIAGNOSIS

Low-grade osteomyelitis.

#### ANATOMICAL DIAGNOSIS

Osteoid osteoma of tibia.

#### PATHOLOGICAL DISCUSSION

DR. MALLORY: Shortly after admission, the patient was seen in the Tumor Clinic, where the consensus was that this was an inflammatory lesion, because of the comparative lack of symptoms, and that biopsy was not indicated. It was suggested that the x-ray films be reviewed again. The patient was later seen at the surgical grand rounds, where, in contrast, biopsy was advised. Eventually it was done. A considerable section of the cortex was removed, cutting down to and including the minute area of rarefaction, which Dr. Lingley believed was there but could not satisfactorily demonstrate in this light. The histologic section has a line of dark red across it, 1.0 cm. in length and 0.4 cm. in width, which corresponds

DR. ALLEN G. BRAILEY: Is the fact that the phosphatase level was normal of any help?

DR. TAYLOR: I should think not. Dr. Franseen has studied these reactions. A high phosphatase level is evidence of osteoblastic activity. We may see a very high one in diseases like Paget's disease, and with some of the osteogenic sarcomas. On the other hand, it may be fairly low in cases of bone sarcoma, especially when there is not a great deal of osteoblastic activity. The low figure in this case might be taken as evidence against osteogenic sarcoma, but I do not believe that it would be indisputable evidence. Some of our osteomyelitis cases have had high phosphatase levels.

DR. CLIFFORD C. FRANSEEN: I agree entirely. The normal phosphatase and the absence of evidence of new-bone formation fit together. That is all one can say.

#### CLINICAL DIAGNOSIS

Osteomyelitis?  
Lymphoma?

#### DR. TAYLOR'S DIAGNOSIS

Pyogenic osteomyelitis.

#### ANATOMICAL DIAGNOSIS

Chronic osteomyelitis of radius (*Staphylococcus aureus*).

#### PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: This patient was operated on, and when the cortex was incised a free flow of pus was obtained. The material curetted from the cavity showed chronic inflammation and no evidence of neoplasm. Cultures of the pus showed *Staphylococcus aureus*.

A PHYSICIAN: What about the urinary tract?

DR. MALLORY: I know nothing more about that. The patient is still convalescing.

#### CASE 27492

#### PRESENTATION OF CASE

A seventeen-year-old Portuguese-American student was admitted to the hospital because of swelling of the left leg.

The patient was well until about six months before entry, when he noticed painful swelling of his right shin. He thought that he had struck the shin against hard objects on several occasions. The swelling gradually increased. After a few months, a local physician was consulted. After a roentgenogram of the leg was taken, a biopsy was requested and refused. Several months later, the patient came to the hospital.

On admission, the patient appeared healthy; the heart, lungs and abdomen were normal. There was a diffuse, bony hard, fusiform swelling on the posteromedial aspect of the left tibia, involving the middle third of the shaft, continuous with the normal portions of the shaft at its margins.

The temperature, pulse and respirations were normal; the blood pressure was 120 systolic, 70 diastolic.

Examination of the blood showed a white-cell count of 13,200 with 74 per cent polymorphonuclears, and a red-cell count of 5,070,000 with 85 per cent hemoglobin. The blood calcium was 11.6 mg. and the phosphorus 3.8 mg. per 100 cc., and the phosphatase was 6.3 Bodansky units. The blood Hinton reaction was negative. The urine was normal. A tuberculin test was negative in a 1:10,000 dilution.

A roentgenogram of the left leg showed a fusiform thickening of the tibia, at the junction of the upper and middle thirds. The periosteum in this area was markedly thickened, and in one or two places there was slight roughening of the periosteum, with some destruction. There was very slight soft-tissue thickening, superimposed. A cavity, measuring 1 by 1.5 cm., situated at the base of the region of periosteal formation of new bone, was visible only on a film that had been much overexposed.

On the seventh hospital day, an operation was performed.

#### DIFFERENTIAL DIAGNOSIS

DR. THOMAS ANGLEM: May we see the x-ray films?

DR. JAMES R. LINGLEY: Here we see the area of fusiform thickening described, which is due mainly to the gross thickening of the cortex on the posterior margin of the shaft. In the overexposed film, there is one small linear area of rarefaction about 1.5 cm. in length within the area of new-bone formation, but I cannot demonstrate it with this light. There is no surrounding soft-tissue mass, and no edema of the soft tissues.

DR. ANGLEM: There is very little in this story that is of any diagnostic aid. It seems to me, as in the last case, that the diagnosis rests on the interpretation of the x-ray films. The essential finding in the history is a story of progressive swelling of the tibia for six months, associated with some pain. At the time of examination, the boy was apparently still in good general health, with normal temperature, moderate leukocytosis—13,200—and a slight elevation in the serum-phosphatase level; otherwise, the findings were essentially negative. We get some assistance from

## INSTRUCTION IN FIRST AID CARE

AN article appearing elsewhere in this issue of the *Journal* calls attention to the importance of instructing laymen in first aid care, not only because of the value of such knowledge in handling the possible civilian casualties of war but also because of its usefulness in giving proper immediate care to the millions of people who are injured each year in automobile and industrial accidents.

Various courses have been sponsored by the American Red Cross, and although over three million certificates have been issued since 1910, it is only within the last two years that the population as a whole, stimulated by the national emergency, has become properly appreciative of what it can contribute if adequately trained in first aid care. Interest has been largely promoted by the

training of thousands of instructors by the American Red Cross, who, in turn, have conducted the classes for civilian defense workers, employees of industrial plants and business establishments, service men and those employed by various local and state governmental bureaus.

Many physicians, unfortunately, seem to have been rather indifferent to this effort—some because of a belief that first aid care cannot be properly given by a layman and others because they are ignorant of what such care comprises. There is no doubt, however, that many of the procedures with which the trained layman is familiar may result in the saving of life or the prevention of severe and permanent crippling, and all physicians should familiarize themselves with the methods of first aid care and should, if possible, register with their local Red Cross chapters as instructors in standard or advanced first aid courses.

A booklet, *Advanced First Aid for Civilian Defense*, has recently been prepared by the American Red Cross in collaboration with the Medical Division of the Office of Civilian Defense. This ten hour course is intended for the personnel of emergency medical field units, for air raid wardens and for members of other civilian-defense groups. Although alone inadequate for nonmedical workers, it furnishes minimum instruction when supplemented by repeated drilling under competent supervision. Physicians who are members of emergency medical field units should conduct the instruction and obviously should be thoroughly acquainted with the contents of the booklet, copies of which can be obtained from the First Civilian Defense Region, 101 Milk Street, Boston.

## CHRISTMAS SEAL CAMPAIGN AND NATIONAL DEFENSE

BECAUSE of the national emergency, the forthcoming Christmas Seal Campaign of the National Tuberculosis Association merits even greater attention and more generous support than the campaigns of other years. Each week brings the European conflict closer. The recent sinkings of American ships in the waters of the Western Hemisphere emphasize the need for more than

vague and half-hearted — and therefore fumbling — program of defense. A united and determined nation, willing to sacrifice temporary comforts and luxuries, must be ready to meet a very real threat. The question of *when* defense is to be achieved now holds little more than academic interest; the question of *how* is all-important.

The crux of the defense effort is good health: a healthy and expertly trained army and navy can be equipped only with the arms produced by industrial workers, who must be protected from sickness; a healthy general population must encourage and support the military and the industrial army — the morale of the whole nation could easily be weakened by widespread disease. Thus, tuberculosis, which still ranks seventh as a cause of death in America and is still the chief killer in the age group that is most vital for national defense, must be eliminated not only from the armed forces and workers in industry, but also from the ranks of those who must endure the restrictions, privations and dislocations of a war-time economy.

The death rate from tuberculosis has been cut 75 per cent since the first sale of Christmas Seals, in 1907. But until the disease has become a curiosity of medical history, — that is, until the death rate has been cut 100 per cent, — there must be no lag in the fight against it; medical knowledge is at present sufficient to stamp it out, but a vast expenditure of money and energy must be available before that goal can be attained. Organizations like the National Tuberculosis Association can function only with the support of the public and the medical profession.

The Christmas Seal Campaign this year presents a double challenge to patriotic and humanitarian impulses: by contributing generously, laymen and physicians can help free the armed forces and the civilian population of tuberculosis, and at the same time they can achieve progress toward the goal of complete eradication, so that in the days of peace a healthy nation can enjoy the liberty, happiness and prosperity it must now fight to preserve.

## MEDICAL EPONYM

### LEGG-CALVÉ-PERTHES'S DISEASE

This condition was first described as an entity by Arthur T. Legg (1874-1939) when he was junior assistant surgeon at the Children's Hospital, Boston, in a paper read at the annual meeting of the American Orthopedic Association in June, 1909. The paper was published under the title, "An Obscure Affection of the Hip-Joint," in the *Boston Medical and Surgical Journal* (162: 202-204, 1910). The author reported five cases, with x-ray photographs, and said:

. . . the following facts . . . are observed:

- (1) Age, five to eight years.
- (2) History of injury.
- (3) Limp.
- (4) Thickening about the neck of the femur.
- (5) Absence of pain.
- (6) Absence of constitutional symptoms.
- (7) Little or no spasm.
- (8) Absence of shortening. . . .

We have considered a group of cases all presenting practically the same conditions . . . which are to my mind atypical of any condition heretofore described. . . . I make no claim to any definite conclusion.

Jacques Calvé, while assistant surgeon of the marine hospital at Berck, wrote a paper, entitled "Sur une forme particulière de pseudo-coxalgie greffée sur des déformations caractéristiques de l'extrémité supérieure du fémur [A Special Form of Pseudotuberculosis of the Hip, with Characteristic Deformities of the Upper Extremity of the Femur]," which appeared in the *Revue de Chirurgie* (42: 54-84, 1910). A portion of the translation follows:

In the past three years, I have had the opportunity of seeing 10 cases of chronic arthritis of the hip that ran a distinctly typical course and were clearly defined both clinically and radiographically, not corresponding to any type previously described and at first considered to be coxalgia, from which they differed in several respects.

As may be seen on reading the notes that we have given at the end of this article and from the examination of the radiographic pictures that accompany them, the chief characteristics of these arthritides are:

- (1) Signs of a reaction about the joint, running a chronic or subacute course and healing without any limitation of motion.
- (2) Bony deformities preceding these articular symptoms and persisting after their disappearance. These are:
  - (a) Coxa vara.
  - (b) Hypertrophy of the head of the femur.
  - (c) Atrophy and lamellar deformity of the center of ossification of the head.
  - (d) Complete absence of bony destruction. . . .

These arthritides occur in young subjects between the ages of three and one-half and ten years

In 1913, Professor Georg Perthes (1869-1927), director of the surgical clinic at Tübingen, delivered an address, 'Ueber Osteochondritis deformans juvenilis [On Osteochondritis Deformans in Young Persons]', which was published in the *Archiv für klinische Chirurgie* (101: 779-807, 1913). He stated that several observers had reported cases of this condition, mentioning his own observation in the *Deutsche Zeitschrift für Chirurgie* (107: 111-159, 1910), under the title *Ueber Arthritis deformans juvenilis [Concerning Arthritis Deformans in Young People]*, but apparently was unfamiliar with Legg's description. He stressed the value of recognizing the nontuberculous nature of the condition. A portion of the translation follows

In this disease, which I should like to discuss here as osteochondritis deformans of the hip in young persons, we are dealing with a peculiar wasting away of the upper epiphysis of the femur, which originates in a subchondral focus of destruction and is complete only after a course of some years. After careful studies, and as the result of work done in company with my assistant, Dr Schwarz, I have arrived at the opinion that in these cases we are dealing with a disease process fundamentally different from the arthritis deformans of adults, and also that the other conception which exists in regard to this condition, namely that it is a tuberculous affection of the upper femoral epiphysis, is not justified. We are rather dealing with a peculiar, unique process, which regularly leads to a characteristic clinical picture and apparently is self limited.

A careful and detailed description of the condition follows, with case histories and x-ray pictures

## MASSACHUSETTS MEDICAL SOCIETY

### SECTION OF OBSTETRICS AND GYNECOLOGY\*

#### FATAL NAUSEA AND VOMITING IN PREGNANCY

A twenty four year-old primipara entered the hospital at the end of the third month, with a diagnosis of nausea and vomiting of pregnancy.

The history states that the patient had been vomiting practically everything for the four weeks be-

fore admission, her weight was 90 pounds, which represented a loss of about 40 pounds. On physical examination, the pulse was 140. There was some tenderness over the region of the liver. An icteric index determination and liver function test showed evidence of liver damage. The patient was given 10 per cent glucose solution intravenously, and four days later it was decided that abortion should be induced. The cervix was dilated, a catheter inserted, and the vagina packed with gauze, in addition to 5 minim doses of pituitary extract every fifteen minutes for ten doses.

On the following day, the catheter and gauze pack were removed, and the fetus was passed spontaneously. Subsequently, the patient did not improve and, in spite of stimulation, died four days later. No autopsy was performed.

*Comment* This case is evidence that, when poorly treated, the nausea and vomiting of pregnancy may still become pernicious and even result in death. Since this patient had had no medical care until she entered the hospital, her death is due solely to neglect on her own part.

Such patients die solely of starvation. Had the patient consulted a physician when the first distressing symptoms of nausea and vomiting appeared and had simple home remedies proved of no value, hospitalization should have been advised. The treatment then would have been rest in bed, sedation, intravenous glucose (2000 cc a day), thiamin chloride intramuscularly in large doses and no food by mouth for several days. Small feedings through a Levine tube might have been necessary, but most patients whose condition does not become too serious recover without tube feeding.

The loss of weight from 130 to 90 pounds shows how poor this patient's general condition was when she arrived in the hospital. The pulse of 140 was another indication of the seriousness of her condition. Abortion, which was the only possible recourse, proved unavailing. Such deaths, when patients are intelligent and consult medical advice, are absolutely unnecessary.

If the statement in the record that, after the catheter had been introduced and the vagina packed, 5 minim doses of pituitary extract were given every fifteen minutes for ten doses is correct, one can only be amazed. Small doses of the drug to stimulate labor after this method of abortion has been attempted may possibly do some good, but large doses are not only contraindicated but might cause harm. Ordinarily, there is no need of using pituitary extract when abortion is done in this manner.

\*A series of selected case histories by members of the section will be published weekly. Come in and question by subscription are solicited and will be discussed by members of the section. Letters should be directed to Dr. Raymond S. T. U.S. Secretary, 330 Dartmouth Street, Boston.

## DEATHS

**BLACKFAN**—KENNETH D. BLACKFAN, M.D., of Boston, died November 29. He was in his fifty-ninth year.

Born in Cambridge, New York, Dr. Blackfan received his degree from Albany Medical College in 1905. He was pathologist and bacteriologist at the Albany Hospital from 1905 to 1907, instructor in pediatrics at the Polyclinic Hospital, Philadelphia, in 1910 and 1911, and assistant at Washington University School of Medicine, St. Louis, in 1911 and 1912. From 1912 to 1918, he taught at Johns Hopkins University School of Medicine, where he was associate professor of pediatrics from 1918 to 1920. He was professor of pediatrics at the University of Cincinnati College of Medicine from 1920 to 1923, and from that time until his death was professor of pediatrics at Harvard Medical School. He was chief of the medical staff at the Children's Hospital, and was associated with the Infants' Hospital. He was a member of the American Academy of Pediatrics, director of the American Child Health Association, and a fellow of the Massachusetts Medical Society and the American Medical Association.

He is survived by his widow and a son.

**LYON**—FREDERICK D. LYON, M.D., of Cambridge, died November 27. He was in his seventy-third year.

Dr. Lyon received his degree from Harvard Medical School in 1896. He was a former member of the Massachusetts Medical Society.

## DEFENSE ACTIVITIES

## UNITED STATES ARMY

The following medical officers entered on active duty between November 15 and 22, 1941:

**BEGG, CHARLES F.**, 1st Lieut., of Providence, Rhode Island; Station Hospital, Camp Edwards, Massachusetts.

**DEL CAMPO, DANTE**, 1st Lieut., of Lynn, Massachusetts; Westover Field, Massachusetts.

**GLENDY, ROBERT E.**, Capt., of Newton, Massachusetts; Station Hospital, Fort Banks, Massachusetts.

**JADOSZ, FRANK C. J.**, 1st Lieut., of Providence, Rhode Island; Army Air Base, Bangor, Maine.

**MORRISON, JONATHAN I.**, 1st Lieut., of Waban, Massachusetts; Westover Field, Massachusetts.

**STARBUCK, GEORGE W.**, 1st Lieut., of Boston; Station Hospital, Camp Edwards, Massachusetts.

**WALKER, DONALD A.**, 1st Lieut., of Worcester, Massachusetts; Army Air Base, Bangor, Maine.

## CIVILIAN DEFENSE

## X-RAY FACILITIES

The Medical Division of the Massachusetts Committee on Public Safety requests that all who operate private x-ray laboratories register with the committee the types of machines they operate, including the current necessary, with additional advice whether, in the event of a national emergency, they would be willing to have their machines moved to hospitals for public use. This information will, of course, be kept confidential, and no action will be taken without consultation with the owners. Communications should be addressed to Dr. Elliott C. Cutler, medical director, Massachusetts Committee on Public Safety, 18 Tremont Street, Boston.

## RADIUM

In England, when an alert is sounded, all who possess radium are required to lower it into a well or pit about 50 feet deep, to do away with the danger that would occur should radium be scattered about in public places. All who possess radium should take some precaution for its proper disposition in the event of bombing.

## REGIONAL MEDICAL OFFICER

Mayor F. H. LaGuardia, director of the Office of Civilian Defense, Washington, D. C., recently announced that Dr. Allan M. Butler, of Boston, had been commissioned senior surgeon in the Reserve of the United States Public Health Service and had been called to active duty as regional medical officer in the First Civilian Defense Region, with headquarters in Boston. The area of jurisdiction corresponds with that of the First Corps Area of the United States Army.

## MISCELLANY

## AMERICAN MEDICAL ASSOCIATION BROADCASTS

"Doctors at Work," the dramatized radio program broadcast by the American Medical Association and the National Broadcasting Company, will go on the air for its second season on Saturday, December 6, from 5:30 to 6:00 p.m., E. S. T. The program is broadcast widely from the more than seventy-five stations affiliated with the Red Network of the National Broadcasting Company and is heard from coast to coast.

Last year, the broadcast was a serialized story dealing with the experiences of a fictitious but typical American boy choosing medicine for his vocation and proceeding to acquire the necessary education and hospital training for the private practice of medicine. Interwoven with the personal story of young Dr. Tom Riggs and his fiancée, Alice Adams, was the romance of modern medicine and how it benefits the physician's patients.

The new series of broadcasts will resume where last year's story left off, namely, with the marriage of Tom Riggs and Alice Adams, and the subsequent life of a young physician and his wife at the time of a national emergency in a typical, medium-sized, American city.

## NOTE

Dr. Russell F. Sullivan has been appointed professor of orthopedic surgery at Tufts College Medical School. He is at present visiting surgeon at the Boston City Hospital.

## CORRESPONDENCE

## ELIGIBILITY FOR SUBSCRIPTION TO MEDICAL-SERVICE PLANS

*To the Editor:* Differences of opinion exist among both laymen and physicians regarding the financial groups to which a prepayment medical-service plan should be available. In a discussion of this subject, the difference between voluntary and compulsory medical-service plans should be kept clearly in mind. This letter concerns itself only with voluntary plans.

Some believe that the Society's prepayment medical-service plan should apply only to the so-called "medically indigent," although it is generally conceded that it is difficult to define medically indigent because so many factors, such as size of the family and character of the ill-

ness, enter into the problem. Limitation of service to this group would mean that the subscribers would be made up chiefly from those who at the present time receive their medical care wholly or in part through institutions supported by taxation or private philanthropy. Students of these plans say that past experience shows that individuals in this group are unable and unwilling to pay such rates as are required to keep the plan from being a financial burden to physicians.

Others believe that service should be available to people in the income level above this charity group which roughly includes those on the borderline of charity up to those in the income level that offers a moderate degree of financial security. Many in this group are anxious not to be objects of charity but still need some method of establishing their financial security by being able to budget for health as well as other expenses. Throughout the country, the medical profession obtains a substantial amount of its income from this group at the present time. Some physicians fear that permitting such persons to become subscribers would make further inroads on their incomes, which have been invaded in recent years by the free clinics because patients have been forced to have recourse to such clinics as good medical care has become more and more expensive. It must be admitted that, if this group is permitted to become subscribers, those physicians who participate will find themselves caring for certain patients who formerly were on a fee for service basis. However, in answer to this, it may be said that, where there have been sufficient subscribers and proper economy in the management of the plan the funds from which physicians are paid have been sufficient to ensure a larger income for the same amount of work among this group than that on the fee for service basis. Furthermore, experience suggests that, under these medical service plans, subscribers obtain more medical service than they are willing to avail themselves of on the fee-for-service basis. It is reasonable to expect that, if the medical-care plan is successfully launched, certain patients from charity or tax supported clinics whose eligibility for such service is questionable will be returned to private practitioners. This will relieve the burden on moneys raised by taxation and the strain on private philanthropy.

Some laymen and physicians consider that prepayment medical service plans should be available to all the population at the same rates, just as hospital service plans are, or any other plans for budgeting the costs of services.

Experience shows that many persons object to subscribing to a medical service plan to which only those with certain incomes are eligible. Some of these objectors fear that this indicates cheap medicine others that it signifies class distinction and thus puts a stigma on them and still others that there must be something wrong with the plan if their superiors in industry are not eligible. With a consideration for these various apprehensions and disapprovals among laymen and physicians, can a simple program be developed regarding who should be eligible to subscribe and on what basis?

This program should guarantee equal service to all subscribers and ensure proper compensation for all participating physicians. It must also be attractive to potential subscribers, because experience has proved that the success of these plans depends on the number of voluntary subscribers, in fact, failure to secure a sufficient number of subscribers on a voluntary basis has been a strong argument for those who favor compulsory health insurance.

Still others believe that, if the plan is open to people of all income levels, there should be a sliding scale of

dues arranged in accordance with the subscribers' incomes. By careful adjustment of rates, it would probably not be necessary to eliminate as potential subscribers those in the higher income levels, because the rates in these levels would presumably be so high that few if any subscribers from this group would be interested. It has been suggested that under this arrangement a physician should receive more for the care of a subscriber who pays a higher rate than for the care of one who pays a lower rate. This seems fundamentally unsound because the amount of time and skill used by the physician toward any subscriber should be the same. The apparent injustice to the participating physician in not being able to obtain a substantial fee from the wealthy subscribers who formerly were patients on a fee for service basis might be equalized by the fact that the funds from which the doctors are paid would be substantially increased if any appreciable number of the subscribers came from the higher income levels, because of the higher rates such persons are charged. Thus, the physicians assured in care for work done under the plan might be appreciably better than on the fee-for-service basis and the physician would still have an opportunity to add to his income by caring on a fee for service basis for those in the higher income levels who would not wish to budget for their medical service.

Such questions as these deserve the careful consideration of physicians. A presentation and tolerant discussion of various aspects of these problems in the *Journal* should contribute much to their ultimate satisfactory solution.

CHANNING FROTHINGHAM, M.D.

Jamaica Plain, Massachusetts

## REPORT OF MEETING

### ROBERT BRECK BRIGHAM HOSPITAL

At a meeting at the Robert Breck Brigham Hospital on October 27, Dr Carl C Seltzer delivered a paper entitled "Anthropometry and Arthritis. The difference between rheumatoid and degenerative joint disease." The report was based on several series of male and female patients who were at the Robert Breck Brigham Hospital either at the time of the study or at some other time. Despite the small numbers involved, the statistics were found to be scientifically significant. The various arthritides were accurately defined, and all cases were clinically assigned to one or the other group.

A study of the racial background revealed that the two groups were composed fundamentally of a cross-section of the surrounding population except for insignificant variations. Had this not been so, the entire study might well have been invalidated. Scrutiny of the age distribution revealed an average of fifty six years in the degenerative group as contrasted with thirty seven years in those with rheumatoid arthritis. Since age might be expected to play a role, a comparison was made between the 12 youngest of the former and 12 of the latter group who were found to be of the same age group.

It was determined that, although body weight may be expected to vary during the course of the disease, the rheumatoid patients were about 30 pounds lighter when measured either by best or admission weight, regardless of age. Similarly, those with rheumatoid arthritis were found to have a greater absolute and relative arm span. The upper body measurements revealed that the rheumatoid patients had narrower shoulders and chest cir-

cumference. Furthermore, the greater chest circumference of the patients with degenerative arthritis was not explained by the weight difference. The same tendency was borne out in a measurement of the intercostal angles, which were markedly narrower in the rheumatoid group.

Examination of the lower torso showed that the rheumatoid patients were also smaller in this region than the other group except in relation to chest circumference. The upper extremities in the former group were shorter in over-all measurement as well as narrower, with very long, narrow hands and a relatively long forearm. The most significant finding in the lower extremities was the relatively small distal femoral intercondylar measurement in the degenerative class.

As a result of these and further detailed statistical analyses of anthropometric measurements and proportions, it was concluded that the patients with rheumatoid arthritis were markedly different in bodily physique from those with degenerative joint disease. These differences persisted even after allowances were made for the age discrepancies between the two groups and the effect of the disease on various parts of the body. On the whole, it appeared that the patients with rheumatoid arthritis were distinctly more linear; they were narrower in the shoulders, chest and hips, and smaller in many muscular circumferences. There were certain anthropometric proportions in which the two groups were so markedly divergent that their frequency distribution showed only slight overlap. Another point of particular interest was the discovery of a strong tapering of the lower extremity among the group with degenerative joint disease. It was found that this type of patient had absolutely and relatively larger bodily dimensions above the hips for the size of the knee and ankle joints.

It was also pointed out that the group with rheumatoid arthritis could be subdivided into several types of body build in which the linear element was fairly strong. The group with degenerative joint disease, on the other hand, consisted mainly of a single type, which was characterized by strong laterality, stocky build and a large-boned, large-muscle and highly pyknic habitus.

The discussion was opened by Professor Earnest A. Hooton, of Harvard University, who stated that it was a statistical miracle that the differentials showed up so clearly with such small samples. He believed that larger groups would undoubtedly corroborate these data and bring out additional smaller but significant data. The suggestion was made that these characteristic body types probably mirror physiologic tendencies, and that an attempt should be made to discover certain physiologic proclivities of normal subjects of the same body types. In general, race is considered of importance only in ruling out the few racial characteristics that might interfere with an evaluation of the individual as such.

Dr. Walter Bauer, of the Massachusetts General Hospital, expected the study to reveal merely a cross-section of the general population and found the results disturbing. In his experience, 100 per cent of people in the sixth decade exhibit evidence of degenerative arthritis. It was stated that there is some difference of degree, the hospital population being the worse and therefore probably representing a selected group.

In closing, Dr. Seltzer stated that there is indeed a mixture of types, which is most marked in the rheumatoid patients, who actually represent the random sample. Dr. Bauer expected the degenerative group to be; the patients with degenerative disease are actually a very homogeneous group. Furthermore, an entirely independent

study in another section of the country gave substantially the same results.

## BOOK REVIEWS

*Lectures on Diseases of Children.* By Sir Robert Hutchison, Bart., M.D., LL.D., F.R.C.P., and Alan Moncrieff, M.D. Eighth edition. 8°, cloth, 471 pp., with 107 illustrations. Baltimore: Williams and Wilkins Company, 1940. \$6.75.

This is not a systematic treatise on pediatrics. It is a transcript of clinical lectures covering, for the most part, the commoner diseases of childhood and such other maladies as manifest themselves more differently in the child than in the adult. A knowledge of general medicine by the reader is assumed, and there is perhaps more emphasis on treatment and general management than on diagnosis.

Obviously, this book is intended to supplement, not to supplant, the usual textbooks. And it contains a good deal of sound, though, to the pediatric specialist, elementary, advice. Of course, in the matter of nonspecific treatments, there often are, even among the ablest of therapeutists, enough grounds for disagreement, and some measures, commonly acceptable, apparently, to our British brethren, are in less favor in this country. Moreover, some of the drugs called for are, at least under the names used in this book, unfamiliar to us. Local trade names, at any rate in a volume intended for foreign consumption, should never be used. It is also to be noted that some of the x-ray reproductions are on so small a scale as to be well-nigh worthless.

The value of this book in England is attested by the fact that it has reached this eighth edition. Unfortunately, it will probably be of less utility here.

*Accidental Injuries: The medico-legal aspects of workmen's compensation and public liability.* By Henry H. Kessler, M.D. Second edition, enlarged and thoroughly revised. 8°, cloth, 803 pp., with 202 illustrations. Philadelphia: Lea and Febiger, 1941. \$10.00.

With the advent of workmen's compensation laws, the medical and legal professions have been forced to develop a set of standards for appraising injuries. Kessler has summarized many of the isolated facts and experiences from the forty-eight states and has created a masterpiece of orderly thought on the numerous problems of accidental injuries.

In this book he gives a brief history of the progress in the field since Wisconsin passed the first state compensation law in 1911. There are many disparities in the present laws of the various states, but these will no doubt be erased as experience points the way to more workable and just legislation.

The introductory chapters are devoted to general considerations of workmen's compensation. There follows a section on specific injuries, which practitioners will find most helpful. Methods of examination, tests of function and evaluation of disability are considered for all types of injury and occupational disease. The facts and opinions collected here are encyclopedic in scope and can save much time in reaching a fair settlement. An extensive bibliography at the end of each chapter will be welcomed by those who wish more information on any specific subject.

## THE PRIVATE PHYSICIAN'S OPPORTUNITY IN INDUSTRIAL MEDICINE\*

J. J. BLOOMFIELD, B. S. T.

BETHESDA, MARYLAND

IN general, when one speaks of a private physician one means a physician who is primarily concerned with the protection of the health of individuals rather than of social groups. He is the physician who, in the course of his practice, is concerned with treating the physical ills, great or small, of patients who come to his office or whom he sees in the home, the clinic or the hospital. To offer his patients the benefits of the most up-to-date and the best medical knowledge, he wages a constant struggle to keep informed of the latest developments in medicine, a science that becomes more and more highly technical and specialized.

Because of the pressure of his practice and because he must keep abreast of technical advances, the private physician may lose sight of the fact that medicine has social and economic aspects, that he may forget that the social causes of illness are just as important as the physical ones, and that he lives and works in relation to a given economic and social system. He may be so absorbed in his work with individual patients that he fails to discern a larger problem—the opportunity and responsibility to serve society.

Yet, if the private physician is to act consciously and intelligently, he must have some knowledge of social and public health problems outside the immediate sphere of his routine practice—problems that he may consider, at first glance, to be completely unrelated to his work. One of these problems is that of industrial health.

All physicians are aware that the United States today is engaged in a program for the defense of its national interests. Furthermore, they know that the core of the defense program is industrial production—the speed with which adequate

quantities of vital defense materials can be supplied. How many physicians, however, are aware of the relation of a high level of industrial health to the attainment of a high level of industrial production? How many realize the nature and extent of the problem of industrial health, and the effect of industrial disability on production? How many recognize that they have an opportunity to help solve these problems and thereby not only to aid in the success of the national defense program, but also to make a contribution of great and lasting social value to the welfare of the Nation?

I shall briefly discuss the problems of industrial hygiene with which the private physician should be familiar, and the efforts that he can make toward their solution.

### *Nature and Extent of the Problem*

According to the latest census, the total labor force in the United States today is approximately 52,000,000—this gives some indication of the magnitude of the problem in terms of numbers alone. So far as the health status of this large group of workers is concerned, despite years of continued improvement in industrial hygiene, industrial accidents in the United States still take an annual toll of 18,000 lives and cause 90,000 permanent and 1,782,000 temporary disabilities. Many problems still arise from diseases peculiar to certain occupations, such as silicosis, lead poisoning and the dermatoses, most of which are preventable.

It is also well known that industrial workers have higher rates of physical defects than non-industrial workers, and that excessive mortality is especially notable in unskilled workers, among whom the death rate from all causes is 100 per cent or more in excess of the death rate among agricultural workers. Of greatest significance, however, is the enormous waste of life and efficiency resulting from nonindustrial illness among workers. As a matter of fact, the amount of

\*Presented before the New England Postgraduate Assembly, Cambridge, Massachusetts, October 29, 1941.

1500 Maryland Avenue, N.E., Washington, D.C.

time lost from work because of ordinary illness is fifteen times as great as the total time lost owing to accidents and occupational diseases combined.

### *Effect of Industrial Disability on Production*

The conditions cited as the cause of disability in industry account for an enormous loss in time—nearly 400,000,000 days a year. The monetary cost of this lost time runs into billions of dollars. In terms of defense materials, this lost time may be interpreted as the number of days it takes to build approximately 50 dreadnoughts of the *North Carolina* class, 165,000 combat tanks or 90,000 bombers. It is true that we know how to control the majority of industrial-health hazards, but it is also true that there is a lag in the application of that knowledge, just as there is a lag between knowledge and its application in other fields. If even a 10 per cent reduction in these time losses could be achieved, it is evident that much would have been done toward removing a serious obstacle to the success of the defense program and toward furthering the health of the Nation.

Needless to say, all these problems in industrial hygiene have become magnified with the present expansion of industrial activities. Preliminary data already indicate a marked rise in the incidence of accidents and occupational diseases among workers. Those who are concerned with maintaining the worker on the job at a high level of health and efficiency have a real responsibility. By creating safe and healthful working conditions *now*, the prospect of being faced in the future with thousands of men and women whose health has been irreparably damaged because of exposure to harmful conditions in industry will be minimized. This, to my mind, is the least we can contribute to the national defense effort.

I cannot presume to discuss mental hygiene, nutrition, the home environment of the worker, housing, and wages and hours, all of which are important aspects that should certainly be included in any serious discussion of the broader perspectives of industrial health.

### *Method of Attack*

Basically, the problems to be attacked can be divided into two types: those concerned with the hygiene of the individual, and those dealing with the environment in which the individual works. The first function comes within the scope of the medical sciences, and the second deals with engineering practices.

So far as the working environment is concerned, it is within the province of the medical profession to determine the existence of such diseases as may

be due to the working environment, whereas on the basis of the physician's findings, the engineer is in a position to learn what unhealthful conditions should be investigated and where control measures need to be initiated. It is essential therefore that the various professions clearly understand the functions of each and approach the solution of the industrial-hygiene problem as co-workers in a joint effort, co-operating with each other to the fullest extent.

Because nonindustrial diseases among industrial workers are just as common as and more serious economically than those among the general population, industrial hygiene has rightfully been considered a function of the general field of public health. It is for this reason that the medical profession plays such an important role, since it is one of the chief concerns of that profession to assist in the promotion of better health in the community.

### *Present Practices in Industrial Hygiene*

Industrial organizations are becoming more and more aware of their responsibilities concerning the protection and improvement of the health of employees. This is especially true of the large plant, which is in a better economic position to deal with this problem than the small plant, which finds it very expensive to provide more than a limited industrial-health service to its workers. Present-day trends indicate that industrial-hygiene services furnished by industry are on the increase and of late have been extended to include not only the prompt treatment of injuries and diseases arising from occupational exposures, but also other services, such as dental, ocular, x-ray and educational programs for health promotion. Many plants have also included programs for systematic study of the working environment in an attempt to control deleterious exposures, and others have established programs designed to diminish the time lost from general illness.

Many nonofficial agencies have of late become deeply interested in the problem of employee health. Some of these agencies, such as the Industrial Hygiene Foundation, are primarily supported by industry itself.

The federal government, of course, has been active in this field for many years. The division of industrial hygiene has been a part of the United States Public Health Service since 1914. Its functions include the co-ordination of all industrial-hygiene activities, both at federal and state levels, the promotion of industrial-hygiene service in state and local health departments, and investigations of a laboratory and field nature. These activities are conducted co-operatively with state

agencies, industry, labor, the medical profession and other professions and organizations.

The growth in the number of state health departments providing services in industrial hygiene has been almost phenomenal during the last five years, under the stimulation of funds provided by the Social Security Act. Today, there are thirty-four states with industrial-hygiene services, employing nearly two hundred and fifty professionally trained persons and spending approximately one million dollars for this activity.

In spite of all this progress, however, actually only a beginning has been made in providing adequate programs for the maintenance of employee health. The United States Public Health Service recently published the results of an analysis of a survey made in approximately 17,000 establishments employing 1,500,000 workers in fifteen representative states.<sup>1</sup> This analysis showed that only 15 per cent of the employees were provided with the services of full-time physicians, and that approximately 22 per cent were furnished the services of part-time physicians or physicians on call. These data are sufficiently representative to show that approximately two thirds of the workers in the United States are without any medical services at the plant proper.

Furthermore, the results of a recent study by the National Industrial Conference Board<sup>2</sup> indicated that in one third of the plants surveyed no efforts were made to supervise nonoccupational disabilities to assure the worker of medical attention. This study also showed that in only slightly more than half the plants was an effort made to promote employee health through educational means, and that only casual supervision was practiced over working conditions.

It may be assumed, therefore, that most industrial workers, when in need of medical services, receive them from the private practitioner—on a part-time basis at the plant, from physicians on call or from the family physician. It is a well-established fact, however, that the physician who spends but one or two hours a day in a plant, as well as the one who merely goes to the plant when called, has not the time to devote to a program of disease prevention.

This state of affairs, therefore, calls for serious consideration on the part of the medical profession regarding its responsibility in the vital field of industrial hygiene.

#### *Possible Contributions of the Physician*

It has been stated by authorities in industrial hygiene that the major needs are medical and surgical care to effect prompt restoration of health and earning capacity following disability, the pre-

vention of disability in industry by the proper control of the working environment and, finally, the promotion of health among workers. For those physicians holding positions in industry, and especially those completely responsible for furnishing programs of industrial-health maintenance, the Council on Industrial Health of the American Medical Association has suggested a definite procedure.<sup>3</sup>

This program consists in such functions as periodic inspection and appraisal of plant sanitation and occupational exposures, followed by the adoption and maintenance of adequate control measures. The provision of first-aid and emergency services and the prompt and early treatment of all illnesses resulting from occupational exposure are very significant functions of the medical department. Impartial health appraisals of all workers and provision of rehabilitation services for the correction of defects are additional functions of a medical department. And, finally, by means of recording and reducing absence due to all types of disability, it should be possible to make real progress in reducing lost time among workers, thereby not only benefiting the worker's physical well-being but also yielding tangible monetary advantages to both employer and employee.

The Council on Industrial Health of the American Medical Association has been very active in stimulating physicians, individually and through medical organizations, to contribute to the health of industrial workers. The council has also suggested the formation of committees on industrial hygiene in state and county medical organizations, and has clearly outlined a program that could be adopted by the state and local societies. The program of activities formulated for these committees comprises the following objectives: to train physicians to recognize and report occupational disease; to train industry and labor to the value of industrial health conservation; to elevate medical relations and standards under workmen's compensation; to scrutinize all social legislation affecting industrial health; to clarify relations between industrial and private practitioners; to improve relations between physicians and insurance companies; and to establish working relations with all state agencies interested in industrial health. I shall elaborate several of these objectives.

It is highly essential that physicians inform themselves further concerning occupational diseases, so that they may recognize such diseases more readily in the course of their practice. It would be advantageous for a private practitioner to make this effort, since he may be called on to

diagnose and treat such ailments in the course of his everyday practice.

It is pertinent to stress one other important item, namely, the necessity for obtaining an accurate and detailed occupational history. It is well known to what great lengths physicians go to obtain an accurate and detailed personal and past medical history of a patient, and yet they often neglect to obtain information concerning the patient's exposure to toxic materials in industry. Because a man's occupation may have a real bearing on his health, it is imperative that a history of his occupation be obtained in detail and interpreted properly. Such an inquiry may often necessitate investigating the patient's working environment or at least obtaining information on this point from the proper plant officials as well as from the patient himself. As an example of the advantage of the occupational history, a recent investigation by the United States Public Health Service indicates that manganese poisoning may often be mistaken for multiple sclerosis or Parkinson's disease.

With further reference to the subject of occupational diseases, it is obvious that unless the physician, whether he is in industry or in private practice, promptly reports to the proper authorities the occurrence of occupational diseases among workers, it will be next to impossible for the official agency responsible for the control of such diseases to carry out its functions. Physicians should adopt the same attitude toward the reporting of occupational diseases that now exists in the reporting of communicable diseases. The recurrence of such diseases may be prevented by a prompt investigation by a state industrial-hygiene service of the conditions in the plant that may include the causative agents. Once these have been established, prompt measures may be taken for the control of the environmental conditions responsible for the diseases.

In addition to these responsibilities, still another obligation should be given consideration. This deals with advising the individual patient regarding his health. The physician is the only one to offer such advice, and it is likely that he will have more success in doing so than anyone else. The patient's co-operation should be enlisted not only in the prevention and control of diseases arising out of the occupation, but also in the promotion of general health and mental well-being.

The physician can make still another important contribution to industrial medicine by stimulating pre-employment and periodic physical examina-

tions of workers in industry, and by calling attention to the necessity for correcting the physical defects revealed by health examinations.

I have repeatedly stressed the need for co-operating with the local health agencies, which are responsible for protecting the health of workers. The private practitioner, either as an individual or through his state or local medical organization, should utilize to the fullest extent the services that may be rendered by the official industrial-hygiene unit, and through it the facilities available in the entire health department. With the exception of Maine, all the New England States today have industrial-hygiene services. Services that may be rendered by the official agencies include: consultation with plant management regarding needed corrections of environmental conditions; advice to the management and medical supervisor concerning the relative toxicity of materials or processes, as well as that of new materials prior to their introduction into the industry; assistance in developing, maintaining and analyzing absentee records; consultant service to medical supervisors, private physicians, compensation authorities and other state agencies regarding illnesses affecting workers; provision of necessary laboratory service; and integration with other public-health bureaus in their programs for workers—for example, the control of cancer, syphilis and tuberculosis.

\* \* \*

I have attempted to define some of the problems of industrial hygiene, the methods employed in their solution and the opportunities that the physician has to make a real contribution toward the maintenance of employee health. I should like to commend to you the thought, expressed by Dr. C. D. Selby,<sup>4</sup> that every physician in industry should consider himself a health officer of that industry. As a matter of fact, I should like to go a bit farther and recommend this point of view not only to the industrial practitioner, but also to the private practitioner in his contact with the industrial patient. It is only by such an approach that progress will be made in efforts to conserve the health and efficiency of millions of workers.

# CLINICAL CLASSIFICATION AND DIAGNOSIS OF HEMORRHAGIC DIATHESSES\*

WILLIAM C. MOLONEY, M.D.†

BOSTON

THE abnormal tendency to bleed has been a medical enigma for centuries, and only within the last few years has some semblance of order emerged from this hitherto chaotic field. Immediate and widespread practical application has followed recent advances in knowledge of the hemorrhagic diatheses, and although, as Nygaard<sup>1</sup> has pointed out, no accurate etiologic classification is at present available, from a clinical point of view it is essential to group these conditions into certain logical categories. In a series of 124 cases of various hemorrhagic disorders, an attempt is made to employ a classification that relates as closely as possible the etiologic and pathogenic factors to the clinical aspects of the disease. Moreover, on this basis, the diagnostic value of certain clinical and laboratory procedures is outlined.

## CLASSIFICATION OF HEMORRHAGIC DISORDERS

Hemorrhage may be considered to occur for only two fundamental reasons—either because of failure of the vascular integrity or because of a defective blood coagulating mechanism<sup>2</sup>; of course, the two conditions may coexist.

## Defective Vascular Integrity

It is customary to divide vascular disorders into nonthrombocytopenic and thrombocytopenic purpuras (Table 1). Unfortunately, owing to inadequate methods of clinical investigation, comparatively little is known about capillary bleeding.<sup>3,4</sup> It is well established, however, that unrelated to platelet deficiency the anatomic and functional integrity of the vascular endothelium can be adversely affected by a variety of agents, such as trauma, lack of vitamins C and P, and various toxic, allergic and metabolic processes. These so-called "capillary purpuras" form the largest group of hemorrhagic disorders, and Quick<sup>4</sup> and, more recently, Haden and Schneider<sup>5</sup> have pointed out that disorders of this type are more significant than coagulation defects from a practical standpoint. Little comment concerning this group is necessary. Subclinical scurvy is commoner than realized; toxic purpuras are of frequent occur-

rence, and if all cases with slight hemorrhagic tendencies were included, the group would be considerably larger. The diagnosis of these nonthrombocytopenic purpuras rests mainly on the history and the fact that clinical laboratory procedures are negative, with the exception of a positive capillary fragility test in certain cases.

Of much more serious implication are conditions in which capillary disturbance is associated with

TABLE 1. Hemorrhagic Disorders Characterized by Defective Vascular Integrity.

Etiology	Clinical Evidence	No. of Cases
<b>Nonthrombocytopenic purpura</b>		
Vitamin C (and P) deficiency	Scurvy	14
Chemical, bacterial or unknown toxin	Purpuras accompanying various intoxications	26
Allergy	Henoch's purpura and those of other types	2
Physical and metabolic defects	Purpura, following heat, cold, trauma, asphyxia and sclerosis	6
Congenital defects	Hereditary capillary telangiectasis	1
<b>Thrombocytopenic purpura</b>		
Secondary to toxic, allergic, chemical or physical agents depressing or invading the marrow	Purpuras accompanying leukemia, pernicious anemia, metastatic bone marrow lesions, aplastic anemia and benzol, x-ray and arphenamine poisoning	25
Idiopathic (splenic or megakaryocytic)	Essential purpura	5
Total		79

a decreased number of platelets. These may be subdivided into secondary and idiopathic thrombocytopenic purpuras. In the secondary type, the platelet reduction is due to depression or destruction of the marrow by toxic, allergic, chemical or physical agents. Severe purpuric manifestations are frequently encountered in leukemia and aplastic anemia. In this study of 41 cases of leukemia, hemorrhagic lesions developed in 16. Purpura of this type also occurs (but less frequently) in neoplastic metastasis to the bone marrow and in pernicious anemia.

The pathogenesis of idiopathic thrombocytopenic purpura remains obscure, owing to the lack of knowledge concerning the role of the platelets and the physiology of the capillaries. Wiseman, Doum and Wilson<sup>6</sup> state that the lack of platelets is the most significant and universal finding in this disorder. The cause of the thrombocytopenia has not been definitely established, but the likeliest

\*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 21, 1941.

Assistant professor of medicine, Tufts College Medical School, junior physician and director of the Blood Clinic, Carney Hospital.

theories are either that the spleen exerts an abnormal thrombocytolytic activity or that in some manner as yet unknown the spleen inhibits the production of platelets by the bone marrow. However, other investigators, especially Elliott,<sup>7</sup> emphasize the role of the capillary disturbance. Until further information is obtained concerning the relation of the platelets to the release of thromboplastin, to clot retraction and to capillary permeability, the problems involved in the etiology of essential purpura will remain unsolved.

Regardless of theoretical considerations, the differentiation of idiopathic and secondary thrombocytopenic purpura is an extremely vital matter. On the one hand, an ill-advised splenectomy will result in disaster, whereas in the properly selected case a dramatically successful cure will often be accomplished. Special emphasis should be placed on a careful history and physical examination, with particular attention directed toward uncovering possible etiologic factors, such as drug intoxication, allergy, infections and lesions involving the bone marrow. In both types of thrombocytopenic purpura, the bleeding time is usually prolonged, capillary resistance and platelets are markedly decreased, and clot retraction is poor or absent. The clotting time is usually normal but in severe thrombocytopenia may be prolonged, and Nygaard<sup>8</sup> points out that the plasma is usually hypocoagulable. Wiseman et al.,<sup>6</sup> in their excellent article, stress the facts that the spleen, liver and lymph nodes are not enlarged in idiopathic thrombocytopenic purpura, and that except for the diminished platelets, unless severe blood loss has occurred, the blood and bone marrow studies are not abnormal. Limarzi and Schleicher<sup>9</sup> strongly advocate bone-marrow studies, and most investigators agree that this procedure is essential before splenectomy.

### Defective Blood Coagulation

In considering the coagulation aspects of hemorrhagic disorders, Quick<sup>4</sup> points out that as a result of the researches of a number of workers a satisfactory hypothesis of the mechanism of blood coagulation is now available. Briefly stated, it is postulated that the plasma contains a protein substance of unknown composition called prothrombin, which is elaborated in the liver through the agency of vitamin K. When blood is shed, this inert substance is converted to thrombin by thromboplastin in the presence of ionized calcium. Thromboplastin is said to be a cephalin-protein complex normally found in the tissues and platelets. Recent work<sup>10</sup> indicates that a substance similar to tissue thromboplastin also exists in the

plasma. As a second phase, thrombin activates soluble fibrinogen to insoluble fibrin. Fibrin acquires the characteristics of adhesiveness, contractility and elasticity, forming the blood clot.<sup>11</sup> On the other hand, it is recognized that certain anticoagulants exist, and although the role of heparin is a matter of debate, it apparently activates the

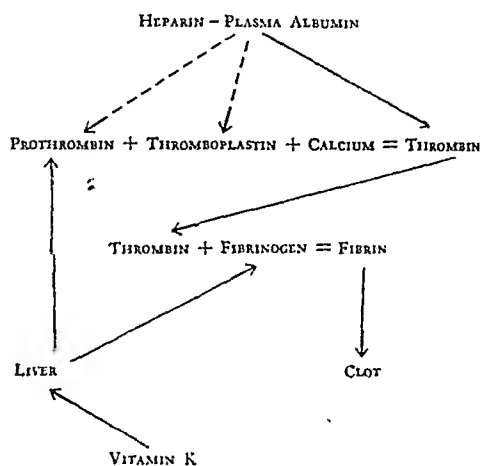

FIGURE 1. *Theory of Blood Coagulation.*

serum albumin to an antithrombic or antiprothrombic capacity.<sup>12</sup> Modified after Quick<sup>4</sup> and Eagle,<sup>13</sup> this theory is diagrammatically expressed in Figure 1.

It may be assumed that any anomaly of the clotting mechanism could result in a corresponding hemorrhagic disorder. Nevertheless, from a clinical standpoint, deficiencies of calcium are unknown, and acquired or congenital fibrinogenopenias are extremely rare.

Of great physiologic and clinical interest is the deficiency of thromboplastin. It is now fairly well established, in large measure owing to the work of Patek, Stetson, Taylor, Pohle and Lozner,<sup>14-16</sup> that hemophilia is caused by a lack of thromboplastin. It is still a controversial point whether this deficiency is caused by an intrinsic lack of a plasma thromboplastin or whether the lack of thromboplastin is due to the slow release from platelets that are abnormally resistant to disintegration. Hemophilia is infrequently encountered in practice, but the characteristic occurrence in the male, in addition to the usual hereditary features and the history of bleeding episodes, makes the diagnosis relatively obvious. Furthermore, the greatly prolonged clotting time associated with normal bleeding time, normal platelet count and clot retraction, prothrombin level and capillary resistance usually confirms the clinical diagnosis. Quick<sup>17</sup> recently pointed out that, in doubtful cases, study of the clotting time of recalcified plasma may yield valuable information.

Hypoprothrombinemia has assumed an increasingly significant clinical role since the advent of vitamin K and the simple laboratory tests for prothrombin. Such conditions are encountered with relative frequency, are usually easy to recognize, and for the most part are amenable to specific therapy. The lack of prothrombin is commonly associated with liver disorders, and it should be emphasized that vitamin K frequently has little effect on raising the prothrombin levels in the presence of continued liver damage. Twelve cases of hepatitis and cirrhosis in this series had intractable bleeding, uncontrolled by vitamin K. From the practical standpoint, the most serious and most commonly encountered hypoprothrombinemias are those due to deficiency of vitamin K either because of lack of absorption from the gastrointestinal tract, as in obstructive jaundice, bile fistula and bowel lesions, or from the dietary lack of vitamin K, especially in hypoprothrombinemia of the newborn.

In differentiating hemorrhagic disorders due to defective coagulation, it is essential, first of all, to

TABLE 2. Hemorrhagic Disorders Due to Defective Coagulation.<sup>4</sup>

ETIOLOGY	CLINICAL EVIDENCE	NO. OF CASES
Calcium deficiency	None known	0
Fibrinogen deficiency	Fibrinopenia	
Congenital	Congenital fibrinogenemia	6
Acquired	Severe liver damage and nutritional and bone marrow disturbances	0
Thromboplastin deficiency	Thromboplastinopenia	
Lack of plasma thromboplastin or faulty release of platelet thromboplastin	Hemophilia vera (2) and sporadic hemophilia (1)	3
Prothrombin deficiency	Hypothrombinemia	
Liver damage	Hepatitis and cirrhosis	12
Deficiency of vitamin K	Deficiency of vitamin K	
Lack of absorption	Obstructive jaundice, bile fistula and bowel disturbances	8
Dietary deficiency	Hypoprothrombinemia of newborn	19
	Total	42

suspect a real or potential lack of one of the constituents necessary for coagulation and, secondly, to investigate the degree and nature of the deficiency by proper laboratory methods (Table 2).

### Miscellaneous Disorders

Less well defined are a miscellaneous group of hemorrhagic states (Table 3) occupying a mid-zone between the capillary and clotting disorders, about which there is inadequate knowledge. These cases often have hereditary or familial characteristics, and various terms have been employed in

designating these disorders, such as hereditary hemorrhagic diathesis, pseudohemophilia and thrombasthenia. In this series, 3 cases were placed in this category. Usually, the clotting time, platelets and prothrombin levels are normal, but there may be prolonged bleeding time, poor clot retraction and decreased capillary resistance. Circulating anticoagulants, including the transitory phe-

ETIOLOGY	CLINICAL EVIDENCE	NO. OF CASES
Unclassified	Thrombasthenia	2
	Pseudohemophilia	1
Intrinsic fibrin defects	Lack of retraction, adhesion and elasticity	0
Presence of anticoagulants	Peptone and anaphylactic shock, unclassified types	0
	Total	3

nomena of peptone and anaphylactic shock, have been reported but are very rare. In this regard, the report of Lozner, Jolliffe and Taylor<sup>18</sup> on a case of a patient with a circulating unidentified anticoagulant is of considerable interest. Another somewhat neglected phase of the clotting mechanism that may markedly influence the occurrence of abnormal bleeding is that of syneresis or clot retraction.<sup>19</sup> Proper retraction, adhesiveness and elasticity are necessary for normal clot formation, and in addition to the physical role of the intact platelets in the clot structure, further study may indicate that the disintegrated platelet or other substances modify the intrinsic retractile properties of fibrin. A recent report by Rabinowitz<sup>20</sup> on the effect of methionine on clot retraction should arouse renewed interest in this aspect of the problem.

### LABORATORY PROCEDURES

In part, the confusion and obscurity attending the diagnosis of bleeding disorders has been due to the lack of application of uniform and relatively simple laboratory tests. Table 4 lists the nature and outcome of such procedures in the major hemorrhagic disorders.

In addition, complete blood studies, the Hinton test and urinalysis should be carried out routinely, as well as special determinations for vitamin C, calcium and fibrinogen when indicated. When performed accurately and subject to proper interpretation and when correlated to the clinical findings, these procedures, which are economically and technically available to practically everyone, should result in a correct diagnosis in all but a few of the most obscure hemorrhagic disorders.

## SUMMARY AND CONCLUSIONS

The various hemorrhagic disorders in the light of recent advances may be grouped into certain logical categories.

In establishing a diagnosis of abnormal bleeding, the value of a careful history and physical exam-

## UNDULANT FEVER IN MASSACHUSETTS

ROY F. FEEMSTER, MD, DR PH,<sup>3</sup> AND GEORGE A. HYDER, MD,<sup>†</sup>

BOSTON

UNDULANT fever was recognized as a clinical entity by Marston<sup>1</sup> in 1861, and the etiologic agent was first observed by Bruce<sup>2</sup> in 1887. In 1897, the name "undulant fever" was given to the disease by Hughes<sup>3</sup>, and in 1905 the goat was found to be the reservoir by Zammit,<sup>4</sup> of the British Commission working in Malta. In the same year, Craig<sup>5</sup> reported the first authentic case of brucellosis in the United States, but the first intimation that the disease was endemic in this country came with the work of Ferenbaugh<sup>6</sup> in Texas in 1911. Some years elapsed before cases were recognized with regularity in New England, but since 1928 the Massachusetts Department of Public Health has been keeping individual epidemiologic records of the disease. Although it was not made reportable until 1930, an occasional case history was obtained in years previous to that time 14 such case histories being on file.

Since the disease was made reportable, 331 cases have been recorded through 1940. Until 1934, no more than 15 cases were recorded in a single year, but after that time more than 40 cases were reported in most years: 1935, 42 cases; 1936, 55; 1937, 43; 1938, 37; 1939, 40, and 1940, 52. No doubt, the principal reason why the number of cases has become higher is that physicians have become more alert in suspecting the disease. This is evidenced by the increase in the number of specimens sent to the State Laboratory for undulant fever agglutination tests. From 1929 through 1940, the numbers of specimens examined in successive years were 167, 280, 401, 339, 374, 457, 742, 1105, 1393, 1871, 1933 and 1996. It must be realized that these figures include a large number of duplicate specimens on the same persons, because in some cases the diagnosis was partly dependent on an increasing titer of agglutination.

It was believed that a summary of the information contained in the epidemiologic records accumulated by the department would be of interest to physicians of the State. In all, 337 histories have been obtained from the 345 cases that have come to our attention since 1927.

It should be pointed out that the information is not at all comparable with that which would be available from hospital records, since in many

cases details are somewhat sketchy, partly because the histories were frequently obtained as soon as the disease was suspected and before all the characteristic symptoms had occurred, and partly because the patients had been seen by several physicians, no one of whom had all the details of the illness. It should also be borne in mind that the primary purpose of the records was to aid in deciding whether the case was really undulant fever, and when it appeared that the diagnosis was justified no further details seemed to be needed.

The inadequacy of the information in these epidemiologic records is indicated by the fact that, after the information available regarding the symptoms, the course of the disease and the laboratory work had been considered, in only 160 cases (48 per cent) was the diagnosis unequivocally justified. On 104 cases (31 per cent), information was less adequate, but it appeared that the disease was probably undulant fever. In 47 cases (14 per cent), from the details available, there seemed to be a possibility that the disease was undulant fever, whereas in 26 cases (8 per cent) information was so inadequate that no opinion was ventured.

*Seasonal Prevalence*

The Mediterranean type of undulant fever in Malta is usually most prevalent in the summer. In Massachusetts, where the disease is largely due to *Brucella abortus* instead of *B. melitensis*, there is very little tendency toward predominance in any season, the cases being fairly evenly distributed throughout the twelve months—January, 29 cases; February, 17; March, 25; April, 24; May, 30; June, 28; July, 27; August, 28; September, 23; October, 36; November, 32, and December, 32.

*Age and Sex Distribution*

On the Island of Malta, the sexes are apparently about equally involved by undulant fever, but in this country there has always been a predominance of males. In our cases, there were 199 cases among males and 85 among females. The comparative rarity of reported cases in the young is likewise borne out by our figures, only 6 per cent of the cases occurring under ten years of age and less than 11 per cent of the total cases between ten and nineteen, whereas each decade thereafter shows approximately double that percentage.

<sup>3</sup>Director, Division of Communicable Diseases, Massachusetts Department of Public Health.

<sup>†</sup>Formerly, assistant epidemiologist, Division of Communicable Diseases, Massachusetts Department of Public Health.

Occupation

In contrast to the observations of Hardy et al.,<sup>7</sup> who found that packing-house employees and workers on farms in Iowa were more frequently attacked, in Massachusetts only 4 of the 270 patients whose occupations were specified were meat handlers; 19 were engaged in farming, and 14 in dairying. The groups most frequently attacked comprise perhaps the largest portion of the population in the State, such as persons engaged in housework, mechanical workers, students, factory workers and clerical workers. This indicates that the method of transmission in Massachusetts may be materially different from that in Iowa. The distribution is one that would be expected if the disease were transmitted by drinking milk.

Fifty-two persons were reported to have had direct contact with cows. In 36 cases, it was not stated whether this was more than the occasional contact of living on a place where cows were kept. In 8 cases, the patient was said to have milked cows, and 8 other patients took care of an aborting cow. Only 1 person was noted to have been in contact with goats alone, and 6 with pigs alone. Undoubtedly, a number of the 52 patients who had been in contact with cows also came in contact with pigs, and a few may have been in contact with goats. However, except for the 8 who were in contact with aborting cows, the disease may very well have been contracted through the drinking of milk rather than by contact with animals.

Prevalence in Urban and Rural Groups

When the cases are tabulated according to the size of the community, it becomes apparent that the smaller the city or town, the higher the rate of undulant fever (Table 1). This distribution of

TABLE 1. *Distribution of Undulant Fever by Size of Community (Massachusetts, 1931-1940).*

POPULATION	NUMBER OF CASES	ANNUAL RATE PER 100,000 POPULATION	PERCENTAGE OF MILK PASTEURIZED
Over 25,000	85	0.3	98.3
10,000-25,000	90	1.2	78.2
5000-10,000	47	1.4	65.0
2500-5000	47	2.4	58.5
Under 2500	56	2.8	?
	325	0.8	85.9

the cases is, of course, also inversely proportional to the use of pasteurized milk, since the smaller the community, the smaller the amount of pasteurized milk used. This points very strongly to raw milk as the source of the disease, which is in line with what would be expected in view of the fact that one sixth of the dairy cattle in Massachusetts are probably infected with Bang's disease.

The same relation is seen when the cases are tabulated by counties. The more rural the county

TABLE 2. *Distribution of Undulant Fever by Counties (Massachusetts, 1931-1940).*

COUNTY	*NO. OF CASES			ANNUAL RATE PER 100,000 POPULATION	PERCENTAGE OF MILK PASTEURIZED

	98	227	325	0.8	86.4

\*Including Nantucket.

and the less the amount of pasteurized milk used, the higher the rate of undulant fever (Table 2).

Symptoms

The six chief symptoms are listed in Table 3. Fever was the most prominent one, being recorded in 84 per cent of the 272 cases in which symptoms

TABLE 3. *Frequency of Symptoms by Sex.*

SYMPTOM	MALES		FEMALES		TOTAL	
	NO. OF CASES	PER CENT	NO. OF CASES	PER CENT	NO. OF CASES	PER CENT
Fever	162	87	65	76	227	84
Chills	86	46	43	50	129	48
Sweats	86	46	27	31	113	42
Weakness	71	38	34	40	105	39
Headache	58	31	22	26	80	29
General aches	44	24	15	18	59	22

were recorded. Chills occurred in nearly half the cases, and sweats and weakness were present in about 40 per cent. The only other prominent symptom was a complaint of general aches, including pains in the joints, muscles, back, neck and shoulders.

Among the many other symptoms mentioned, some were no doubt associated with the brucellar infection, but others may have been due to coincidental conditions. These symptoms, in order of frequency, were: malaise, 43 cases; loss of appetite, 34; loss of weight, 28; nausea, 19; listlessness, 17; abdominal pain, 12; vomiting, 7. Dizziness, restlessness, insomnia, prostration, diarrhea, cough, dyspnea and a few other symptoms were mentioned occasionally.

An attempt was made to estimate the severity of the symptoms. Nearly three quarters of the cases appeared to be moderate in severity, less than 10 per cent were severe, and the remainder

were mild or subclinical. Symptoms were slightly milder in females than in males. Age seemed to have little influence on severity except that, in patients under ten years of age, the cases tended to be either mild or severe, the proportion of moderately severe cases decreasing to less than 50 per cent; in the older ages, about 75 per cent of the cases were moderately severe.

Another criterion of the severity is the delay in the discovery of the cases as measured by the time elapsing from the onset of symptoms to the reporting of the case. One would expect that the milder the symptoms the greater the delay. Nearly half the cases were not reported until from one to three months after onset, and in about one eighth the delay was even longer. The fact that among females there was a longer delay after the fourth week indicates either that the symptoms were milder or that the infection was more frequently confused with some other disease in that sex.

#### *Agglutination Tests*

Of the 178 cases in which the results of agglutination tests were recorded, 109 showed positive reactions in dilutions from 1:135 to 1:1215 inclusive; 44 showed positive reactions in dilutions greater than 1:1215, whereas only 6 showed positive reactions in dilutions less than 1:135. In 19 cases, it was stated merely that the agglutination was positive, and no titer was given. There was no significant difference in the distribution of these varying degrees of agglutination by age. In 169 cases, it was possible to estimate the time that elapsed between the onset and the last test performed. Two patients in whom the titer was less than 1:135 were tested only early in the disease. As would be expected, those in whom the last test was less than four weeks after the onset of the disease tended to have titers somewhat lower than those in whom the last test was made after that time. There was no marked difference in agglutination tests in the two sexes.

#### *Probable Source of Infection*

It has already been noted that only a few cases can be explained by direct contact with infected animals. For this reason, considerable attention was directed to the source of the milk supply of those who became ill. Table 4 gives the kind of milk that was used regularly. It will be noted that almost 80 per cent of the patients gave a history of using raw milk regularly, less than 10 per cent used pasteurized milk regularly, and about 11 per cent made no statement about the regular milk supply. Many of these patients, in addition

to using milk from their regular supply, obtained milk on occasion from other sources. Twenty-five per cent of those who had a secondary milk supply used raw milk either occasionally or frequently.

An analysis of the 32 cases in persons who claimed that their primary milk was pasteurized is illuminating. Fourteen of these obtained raw

TABLE 4. *Kind of Milk Used Regularly in Reported Cases of Undulant Fever.*

KIND OF MILK	NO. OF CASES	PER CENT
Raw	215	63.8
Raw and pasteurized	52	15.4
Pasteurized	32	9.5
Not stated	38	11.3
	337	

milk from secondary sources, 7 frequently and 7 occasionally. Eleven of the remaining 18 were recorded as not having used any raw milk. Of these, 2 had handled aborting cows, 3 had handled carcasses of animals, 1 worked at a piggery where other cases of undulant fever had occurred, 1 had no symptoms, and 1 showed a positive agglutination reaction after a skin test had been performed; in the remaining 3, there was suspicion that raw milk had been used. Seven of the 18 histories contained no statement concerning a secondary milk supply. Of these, 3 patients were in contact with cows or pigs, 2 may have become infected from cheese, the diagnosis was questionable in 1 case, and the last patient probably used some raw milk.

An analysis of the 38 cases in which there was no statement about the primary milk supply is also of interest. Fifteen of these patients lived in communities in which pasteurized milk was not regularly available, and it is logical to conclude that they used raw milk. Eight others used raw milk from secondary sources. Two had handled aborting cows, 1 was a laboratory infection, 5 had no record of a confirming agglutination test, and in the remaining 7 the use of raw milk could be neither excluded nor verified.

In many cases, information was collected about the dairy herds when a raw milk supply was involved. Records concerning 93 herds in which abortus testing had been done were available. Eighty-six of these herds showed reactors, only 7 being entirely free of Bang's disease. In 175 cases, there was a statement of whether abortions had occurred in the herd; in 76 (44 per cent), the answer was in the affirmative.

### *Relation of Prevalence of Undulant Fever To Milk Regulations*

Since undulant fever was not recognized in Massachusetts before about 1920 and was not recorded regularly until after 1930, it is impossible to submit statistics to show whether the disease has been increasing or decreasing. It is believed, however, that the prevalence of undulant fever has declined in the same manner as that of other milk-borne diseases as the quality and safety of milk supplies have improved.

The great impetus to place safeguards around milk in Massachusetts was given by the epidemics of milk-borne septic sore throat that were striking one community after another in the years immediately following 1911. The use of pasteurized milk increased progressively, occasional outbreaks of milk-borne diphtheria, scarlet fever and typhoid fever giving further emphasis to the need for such safeguards. The large outbreak of nearly 1000 cases of septic sore throat, with 48 deaths, in Lee in 1928, however, initiated action by local boards of health to require pasteurization or certification of all milk sold. Beginning with Boston in that year, one after another of the communities in the State have required that only safe milk may be sold, until at the present time seventy-seven communities, representing almost 80 per cent of the population, have regulations requiring pasteurization or certification of all milk sold.

The number of outbreaks traced to milk has progressively decreased with the increased use of pasteurized milk. From a peak of forty-five outbreaks, with 4255 cases, in the five-year period 1911-1915, the number has dropped to 4 outbreaks, with 331 cases, in the five-year period 1936-1940. No deaths have resulted from epidemics of milk-borne disease in the last five years. No cases of diphtheria have been traced to milk since 1925; the last milk-borne outbreak of typhoid fever occurred in 1932; and the last scarlet-fever outbreak due to milk was in 1933. The outbreaks during the last five years were due to streptococcal sore throat and undulant fever, all on raw-milk routes.

It is estimated that almost 90 per cent of the milk sold in the State is now pasteurized. Other communities are expected to pass regulations requiring pasteurization or certification in the near future, making the prospects good for a further decrease in milk-borne disease.

### SUMMARY AND CONCLUSIONS

A summary is given of 337 epidemiologic case records from 345 cases of undulant fever in Massachusetts occurring since 1927.

The number of cases reported has increased, probably owing to an increased alertness of physicians in recognizing the disease. The number of agglutination tests for undulant fever performed by the State Laboratory has rapidly increased.

There is little tendency for cases to predominate in any season.

The age and sex distributions parallel those reported from other parts of this country.

Danger of infection is not limited to any particular occupation in Massachusetts.

The disease is most prevalent in rural areas where little pasteurized milk is sold.

Most of those ill of the disease give a history of the use of raw milk, either regularly or occasionally.

With almost 80 per cent of the population of the State living in communities requiring pasteurization or certification of all milk sold and with almost 90 per cent of the milk consumed already pasteurized, milk-borne disease can be expected to remain at a low level.

## COMMUNITY SUPERVISION OF MENTAL DEFECTIVES IN MASSACHUSETTS\*

NFIL A. DAYTON, M.D.,† AND MARION A. NUGENT, A.B.‡

BOSTON

FOR many years, mentally defective children have been referred to as "institutional problems." This belief has come into being since 1848, when the first state school was opened in Massachusetts. Quite commonly, physicians, nurses, social agencies and practically all social workers have as sociated mental deficiency with institutional placement. The resultant concentrated demand has created crowded state schools and long waiting lists. With institutional care as the advocated and generally accepted solution of the problem, the possibilities of community adjustment of mental defectives have received scant attention. Paradoxically, this situation has come about in spite of the fact that community supervision by parents, and satisfactory supervision in all but a few cases, had been going on long before the establishment of state schools. What is the history of community supervision, and what are the possibilities of community adjustment of mental defectives? Is there any other answer than institutional care for cases of mental deficiency?

In 1915, the state schools of Massachusetts<sup>1</sup> began to experiment with the thought of placing trained boys and girls in the community at wages. This was started with some diffidence since, up to that time, there had been a rather firm belief that mental deficiency was a permanent institutional problem. In fact, the late Dr. Walter E. Fernald once said that no mental defective should be released from a state school. After he saw some of the work being done at the Wrentham State School by Dr. George L. Wallace, he<sup>2</sup> had an extensive study made of the outcome of boys and girls who had left his school at Waverley and returned to the community. These children had been removed from the school against Dr. Fernald's advice. He found that many had turned out favorably, and that his pessimistic predictions of earlier years had not been justified.

For the last twenty-five years, state schools have conducted a parole program for girls and boys who have been able to profit by the training offered by the schools. They are placed in paying positions in the community and are supervised by

the social workers of the respective schools. At the end of 1940, 233 girls and 106 boys were on parole from the Fernald, Wrentham and Belcher-town state schools. The 339 on parole earned a total of \$45,747.84 during 1940. This is an average of \$134.95 for each, or an average weekly wage of \$2.60 in addition to maintenance. This amount is not large, but when one realizes the rather limited accomplishments of many of these boys and girls, it is not unreasonable. The main thought to be preserved is that children once considered total losses economically and socially, because of mental deficiency, have now been made into self-supporting citizens. Monthly checking by the social workers of working and living conditions, wages received and other financial exchanges between employer and employee obviates exploitation.

During the last fifteen years, however, another type of community supervision has come into being. The overcrowding of the three state schools has made it impossible for children seeking admission to receive the desired training in such a school. Complicated social problems and difficult home situations have been observed in many of these children. There is urgent need for early admission, but the impossibility of admitting more children to already overcrowded buildings is obvious. In this situation, it has become necessary that the Department of Mental Health take some means to offer at least temporary relief. The suggestion for a plan of community supervision by the department came from Dr. Fernald himself, thus showing the willingness of a great man to reverse a former decision. In 1921, Dr. Fernald in collaboration with Dr. George M. Kline, at that time the Commissioner of Mental Diseases, elaborated the statute (Section 66A, Chapter 123, of the General Laws) that legalizes the commitment of feeble-minded persons to the department for community supervision. The original bill was amended in 1924, when the division of mental deficiency, whose personnel comprised a psychiatrist, two social workers and one stenographer, was created within the central department. Since then, the number of social workers has been increased to three. From time to time, the supervisory work has been expanded, developed and

\*From the Massachusetts State Department of Mental Health and the Department of Psychiatry, Tufts College Medical School.

†Director, Division of Mental Deficiency, Massachusetts State Department of Mental Health.

‡Psychiatric social worker, Division of Mental Deficiency, Massachusetts State Department of Mental Health.

altered to meet the new and changing needs of the community.

Mentally defective children are referred for supervision by public and private agencies, as well as by individuals. The patients carried by the division fall into six general groups. In the following discussion, the different groups are arranged in accordance with the ages at which the patients are referred, the youngest being considered first.

#### GROUPS OF PATIENTS

##### *Home-Training Group*

The home-training children are the youngest placed under our care. They include children of preschool or school age, with mental ages from two years or less to about six years. Because of their low mentality, these children have been refused admission to school, or have been excluded from regular classes or special classes. They are at home without anything to occupy their time, and the parents need advice and help in providing necessary training. In other situations, children are awaiting admission to a state school. Owing to overcrowded conditions and the resulting long waiting lists, immediate admission is not possible. Thus, some definite plan to promote the adjustment of the child in his own home is urgently necessary.

Since 1937, home training and teaching lessons have been provided to aid these children. Outlined lessons and materials have been prepared for the following three classifications: Group A, mental age less than two years; Group B, mental age two to four years; Group C, mental age four to six years. A complete psychologic and mental examination is obtained early, since it aids the worker in assigning lessons and materials suitable to the mental age of the individual child. The social worker visits the home each month, and outlines and teaches a new lesson to the child and the mother. The parent then continues the lesson work for an hour or two each day. The successive lessons that make up the child's "school book" are printed on paper of different color and used primarily as a teaching aid for the parents. The attractive colored materials for the carrying out of each part of the lesson are provided at a minimum cost to the parents, or are supplied gratis if circumstances warrant.<sup>3</sup>

After learning to do simple handwork suited to his mental age, the child gains proficiency and is able to occupy himself in a constructive manner. He soon reacts to success in these tasks and almost invariably becomes a better adjusted member of the family group. In addition, the teaching of the lesson work by the parents often gives them their first real understanding of their child's mentality.

From that point on, they begin to plan for him on his own mental level. During the visits, the parents have frequent opportunities to discuss with the social worker any problems or conflicts arising in connection with the adjustment of a mentally deficient child. Institutionalization of many children has been postponed. As the child becomes adjusted in the home, the parents show less interest in placing him in an institution. In several cases, children previously excluded from school have shown great progress. After one or two years of home-training lessons, during which they have learned color, numbers, letters and simple school work, some of these children have improved so much that they have been able to return to special classes and remain in school indefinitely. About 55 of these boys and girls are being supervised by the division, and the referrals to this particular group are increasing each year.

##### *Special-Class Group*

The special-class group comprises children now being cared for within the public-school system. After examination by a traveling school clinic, the psychiatrist in charge may recommend special-class placement and social supervision. The divisional social workers visit the home and explain to the parents the difficulties experienced by the child in school and the advantages offered by the special class. In this way, the parents gain an understanding of the value of special-class training and how it may influence the development of work aptitudes on the part of the child. Very often, the parents have many other questions and problems to discuss with the social worker. Recreation, summer-camp placement, medical care and other assistance are included in the supervision of these boys and girls when the parents cannot arrange for them.

With older children attending special classes, analyses are made by the social worker and school teacher to plan vocational training and placement. After leaving the special class, the patient may be carried for supervision or placed in a training home. The child may be discharged if it is known that he is being satisfactorily cared for by the family or an agency.

##### *Training-Home Group*

Cases placed in training homes prior to wage placement are made up of girls seventeen to twenty-five years of age who have reached their capacity in regular-class or special-class work. The intelligence quotient ranges from 58 to 69. Some have been removed from unfavorable homes and environments, have no parents, and are under the complete care of the Department of Mental Health

as committed cases (Chapter 123, Section 66A, of the General Laws). Others have interested parents who pay all expenses incurred by their daughters in the training home, and are classified as voluntary cases. The training-home supervision and the medical, dental and recreational care are the same for both groups. The girls are placed in carefully selected and thoroughly investigated homes with an understanding foster mother who gives special instruction in housework, care of children, cooking and general training. The goal of future wage placement is emphasized at all times.

The social worker and the foster mother plan a course of training, which is carried out daily in the home. The progress and failures of the girls are checked frequently by the social worker through interviews. At regular intervals, the girls are instructed to make a record of their daily duties. Their accomplishments, attitudes, general appearance, conduct and progress, as well as their failures, are noted by the foster mother on the same report. In this way, knowledge of their efficiency and progress is gained and recorded. The girls are encouraged to attend church, 4-H clubs and suitable community activities where understanding persons are in charge. Protection and good influence are very valuable for retarded girls of these ages, since they are very impressionable and show the same response to either constructive or destructive influences. Under the present plan, two or three girls are placed in a training home, and a definite schedule of training for each is worked out with the foster mother. With frequent check-ups, the social worker can evaluate progress and judge how soon the girl will be ready for placement in a wage home.

The training requires from six months to two years, depending on the mental level of the patient. The annual expense of about \$350 is small if one considers that the training makes a self-supporting worker out of a potential dependent. To date, there has been a greater demand for girls trained in housework than the division could supply. As soon as a girl learns the basic routine in a training home, it is almost certain that there will be a suitable home waiting for her in the community.

#### *Wage-Earning Group*

The cases in the wage-earning group have comprised the principal type of supervisory work since the beginning of the division. Until recently, there were no funds for training potential wage earners. As a consequence, only retarded young women who gave indication of their ability

to work and support themselves could be accepted for supervision. These women are usually from twenty-one to thirty years of age, with an intelligence quotient ranging from 60 to 69. They are accepted as either committed or voluntary cases, depending on their background and circumstances. After a thorough investigation, the woman is placed at wages in a home in which it is thought that the employer and other circumstances will favor adjustment. She receives room, board and wages commensurate with her ability. Some have begun with wages as low as \$1.00 a week and progressed to \$8.00 a week. The average wage is between \$3.00 and \$4.50 a week. At the outset, the employer is informed frankly of the young woman's characteristics, plus or minus. She is also instructed in the art of dealing with the mentally deficient, if it happens that she has not had previous experience with them. She is told also of the part the employer must play in the supervision program and the regulations required by the department.

Each month, the employer returns to the division a wage report, which has been signed by the woman. This states the employee's wages, the weekly spending money given to her and the remaining amount sent in for banking. Her banking and purchases of clothing, and her medical, dental and recreational care are supervised by the social worker, who makes frequent visits to the employer and the employee to discuss any problems that may come up. In some cases, it has been necessary to make changes after a time and place the woman in a new working home. In these cases, another young woman is placed with the original employer. Most of these changes have worked out to the advantage of both the employer and the employee.

Experience with the wage-earning group has taught us that mental defectives, with supervision, can be influenced to carry on in the community as responsible, self-supporting citizens. Without guidance, they are easily swayed by doubtful influences and may become community responsibilities rather than assets.

#### *Family-Care Group*

The boarding-out or family-care cases have been placed by the division since 1938, when funds were appropriated for this purpose. Board is paid for two different types of patients: those who are potential wage earners and have already been described in the group trained in homes prior to wage placement; and those who constitute typical institutional cases of the lower mental ratings, with no ability for work training. Because of the overcrowded conditions of the state schools,

it has been necessary to provide boarding care for a few girls on the waiting list who cannot be continued in their homes. Surprisingly, it has been found that certain mental defectives may become satisfactorily adjusted in another home, although they were making no progress whatever in their own homes. In general, boarding care is less expensive than state-school maintenance, although the margin is not great.\* If the patient is committed to the department, the State pays the board. If the commitment is voluntary, the board is paid by relatives. In either event, the social worker investigates possible homes and selects the one considered most suitable for the patient. The foster mother is told frankly about the type of patient who is to be placed with her, and is given full opportunity to decide whether she desires to assume such a responsibility.

After a patient is placed in a home, the social worker visits frequently to aid the patient in adjusting herself to the new surroundings, and to assist the foster mother in understanding and dealing with the many problems associated with the mentally deficient. The patient's medical and dental care, clothing and recreation are supervised by the social worker. Arrangements have been made with state hospitals near the boarding homes for the patients' medical and dental care and for their attendance at church services and recreational programs.

The patients placed out during the last two years have been those of the imbecile level, with intelligence quotients between 35 and 49. Chronologically their ages have been from sixteen to sixty-eight years. For example, a girl sixteen years of age could not adjust herself to her own home, and institutional care seemed imperative. Because the state schools had no space available, the division was asked to find a suitable home. The board and all expenses were paid by her family. She has made a good adjustment in a quiet home with an understanding and patient foster mother. Two men, both sixty-eight years of age, who had been in a state school for over forty years, were transferred to the division and placed on a farm where their board was paid by the State. Both men have intelligence quotients around 50 and enjoy little duties, such as feeding chickens and simple chores. They have made a good adjustment in their new homes and are extremely happy. One wonders whether or not the forty years within an institution were necessary.

Although the boarding-out plan is a new ven-

ture for the division, it has been very successful. Overcrowded state institutions and long waiting lists demand an answer. Patients who have benefited from years of training and discipline at a state school but are not suitable for wage placements do very well. This is not only a very happy change for the patient but also effects a small saving for the State. In other cases, mental defectives who are poorly adjusted in their own homes because of unalterable circumstances make unexpected adjustments in foster homes. The family-care plan lessens the expense to the State and makes room in the schools for patients who cannot be cared for except by institutionalization.†

#### *General Supervision and Consultation Group*

The general supervision and consultation cases are referred by various public and private agencies as well as by individuals. The patients under general supervision are often older boys and girls who do not classify in any of the other five groups. Usually, they are being cared for in their own homes. Their parents or relatives are able to take care of their physical needs, but require guidance and assistance from time to time in dealing with the difficulties and problems associated with mentally deficient children or adults. Even an occasional contact with the patient and his family has been found to have a stabilizing effect on the family situation.

Consultation cases are those in which the division acts as an adviser to the referring agency or family. After investigation, the patient may be found to be suitable for supervision in one of the five groups already described. On the other hand, by reason of legal and financial limitations, the division cannot assume the care of certain types of cases, such as defective delinquents, patients incapacitated by severe physical infirmities and patients suffering from mental disease. Anyone referring such cases is directed to organizations that deal with these specific types. Likewise, cases of extreme mental deficiency, which cannot be supervised in the community by the division, are referred to state schools as urgent institutional cases.

Many family and children's agencies recognize mentally deficient cases among their clients and seek advice from the division. First, a complete mental and physical examination is made. A complete picture of the patient is arrived at by means of social and educational investigations, and also by physical, mental and psychological examinations.

†Family care from a state school was placed in operation in 1938, by Dr. George E. McPherson, superintendent of the Belchertown State School. About 50 older patients are being carried in suitable homes in the community. The beds vacated thus become available for younger and trainable patients on the waiting list. This service is in addition to the usual parole placements at wages being carried out at Belchertown.

\*The annual expense (\$350) for boarding care may be analyzed as follows: board, \$234; medical and dental care, clothing and so forth, \$90; social supervision, \$26. Annual charges for maintenance for 1940 in state schools were \$363 per patient.

After this procedure, the diagnosis, prognosis and course of action are summed up and discussed at a staff meeting. The referring agency is often willing to carry on the supervision if it may consult the division from time to time. The division co-operates with many community social agencies, schools, churches and clubs, and with individuals who seek advice about mentally deficient children or adults.

#### LEGAL STATUS OF CASES UNDER SUPERVISION

Committed and voluntary status has been mentioned in describing the different placement groups. When the department indicates its approval, any mentally deficient person may be committed to the Division of Mental Deficiency for supervision.\* The six types of cases outlined previously may be supervised on the voluntary status, but ordinarily the committed cases are placed in training homes prior to wage placement, in the wage earning group or the boarding out or family care group. The Division of Mental Deficiency, by law, has the complete care and supervision of the patient, including supervision of the patient's funds. In most cases, commitment is used because the patient has no suitable person to look out for his welfare. If he is under the family care plan, his board and maintenance are paid by the State. However, the majority of the committed cases are self-supporting. The voluntary cases usually have relatives who are able to take the financial responsibility but need assistance in the care and supervision of the patient in the community.

#### COMMENT

The six classifications of cases supervised by the division show the scope of work being done for the 300 cases of mental deficiency supervised in the community. In the early stages of this work, about fifteen years ago, mental deficiency was not recognized so promptly as it is at the present time. The examinations and diagnoses of mental deficiency by the traveling school clinics by the outpatient clinics of the state mental hospitals and schools and by the habit clinics have brought

about a growing awareness among private and public agencies, as well as the general community, of the problems of mental deficiency. Consequently, younger patients are being referred to state schools, clinics and to the Division of Mental Deficiency each year. The shift in type of case referred has changed the emphasis to supervision of the younger mentally deficient. In many cases, early recognition of the condition and helping parents to understand their retarded child have effected a satisfactory adjustment of the child in his own home and have indefinitely postponed institutional placement. When home adjustment is impossible, training homes and boarding homes have proved to be satisfactory as well as economical, and have taken some of the burden that previously went to the institutions.

When one realizes the growing number of recognized mentally deficient persons, it seems altogether reasonable that every possible plan be made to start the training of this group at an early age so that the number of maladjusted mental defectives may be kept at a minimum. Public and private agencies are showing an increasing interest in arriving at a complete understanding of this problem. The assistance they can offer should be developed to the greatest degree, since the care of mental defectives must become more of a community responsibility as time goes on. At the end of 1940, a total of over 54,000 mental defectives were known to the Department of Mental Health, through its Central Registry of Mental Defectives. Over 4,000 new cases of mental deficiency are being discovered each year. The Commonwealth can never assume the cost of providing institutional care for all this group. Many mental defectives require institutional care, but that is not the answer to the problem of mental deficiency, taken as a whole. The development and success of community supervision of mental defectives have proved its practicability. An increase in the personnel of the Division of Mental Deficiency is urgently needed to extend the work on a state wide basis. The Commonwealth should do everything possible to assist mentally deficient persons to a satisfactory social and economic adjustment in the home and in the community. Institutionalization should be the last thought, after all other resources have been exhausted.

\*Sec on Gen. Chapter 123 of the General Laws reads: "Commitment to Department. If an alleged feeble-minded person is found upon examination by a physician qualified as provided by section fifty-three to be a proper subject for commitment, the judge of probate for the county in which such person resides or is found may upon application commit him to the custody or supervision of the department, but no person shall be so committed unless the approval of the department shall be filed with the application for the commitment. If he is committed to the custody or supervision of the department, the department shall thereafter have power whenever advisable to transfer him to a state school for feeble-minded or may cause an application to be made for his removal to a department for defective delinquents and such person may be so removed in the manner provided by section one hundred and sixteen. If the alleged feeble-minded person is committed to the custody or supervision of the department of mental diseases, the said department may temporarily release him in the manner provided by and subject to the provisions of section eighty-eight, or may discharge him under section eighty-nine."

DIABETES INSIPIDUS IN ONE OF TWINS\*

HARRY BLOTNER, M.D.†

BOSTON

IN the course of an investigation of a group of 30 patients with diabetes insipidus, I found that one patient, now an eighteen-year-old boy, had a nonidentical twin sister who did not have this disease. The twins differed so markedly in stature, general configuration and progress of growth that it appeared of interest to present their cases.

CASE REPORTS

*John's history.* John has had diabetes insipidus since the age of 5½ years, and I have observed him for the past 7 years. He was born 10 minutes before his twin sister. He and his twin each weighed 7 pounds at birth and were of normal height. The delivery, like the pregnancy, was normal and was performed at home without instruments. The patient had a healthy infancy and gained moderately well. He has had a pigeon breast since birth; he was given cod-liver oil from the age of 3 months, and orange juice until he was 3 years old. He developed his first tooth at 6 months and walked at 15

had become deeper, and there was a beginning growth of hair on the face and a considerable growth of pubic hair, although it had a female distribution. The penis was 5 inches long, and he had daily erections; the testes, too, were normal in size.

Physical examination was not remarkable, except for stunted growth. The basal metabolic rate was -9 per cent at the age of 14 years.

The laboratory data are given in Table 1.

*Joan's history.* Joan's birth was normal, and she had a healthy childhood and normal subsequent maturity. She had a normal growth, unlike her twin brother. She is now a tall, well-built and attractive girl. She was bright at school and graduated from high school at the age of 17 years. She has a pleasant personality, in contrast to John. During her childhood, she had much the same diet as her twin brother.

The menses began at the age of 13 years, and they have been regular and normal since then. The basal metabolic rate was -19 per cent at the age of 14 years. Physical examination is entirely negative.

*Family histories.* The father, mother, three brothers and one sister appear to be well and normally developed. There is no history of diabetes.

*Comparative physical characteristics of the twins.* The difference in the general appearance of these twins has been striking, as illustrated in Figure 1. Joan, at the age of 18 years, is a well-developed, mature girl who is about a head taller and 25 pounds heavier than John, who appears stunted in growth and underdeveloped.

Table 2 presents a record of the progress of the twins' height and weight at intervals of approximately 1 year.

*Comparative x-ray studies of twins.* When the twins were 14 years old, x-ray films of the skull and right hand

months. He had measles, mumps and chicken pox. About 6 months before the onset of the diabetes insipidus, he hurt his head, which raises the question whether the injury had anything to do with the precipitation of the disease; x-ray studies of the skull were negative. At the onset of the disease, the daily fluid intake and output were 3 to 4 liters, and he voided about every 15 minutes. When he was about 8 years old, his mother noted that he was not growing so fast as his twin sister, and as time went on, this difference in weight and height became more marked. Like his twin, he did well at school until his second year at high school, when he did poorly; he had to withdraw from school the following year. At the age of 11 years, the daily fluid intake and output without pituitary therapy were about 6 to 7 liters—at present, these are about 9 to 10 liters. Pituitary extract administered intranasally or intramuscularly has always reduced the urine volume to normal. At 18, his physical development was retarded, and he had not matured sexually; he did not have to shave. He had become extremely sarcastic. Six months later, however, the patient showed marked sexual changes and had become considerably calmer. His voice

17	60½	81	64½	106
18	62	85	66	111

and wrist were obtained to determine whether there was any difference in their bony development. The reports were as follows:

Films of John's skull shows a smooth vault, with no localized changes or signs of pressure; no abnormal calcification is seen and the dental development is

\*From the Medical Clinic, Peter Bent Brigham Hospital.  
†Associate in medicine, Peter Bent Brigham Hospital.

normal. In the film of the right hand and wrist, all the epiphyses are wide open.

Films of Joan's skull show it to be normal; it is 0.8 cm. greater in anteroposterior diameter than that of her twin. There is no appreciable difference in the dental development. A film of the right hand and wrist shows that the epiphyses of the terminal pha-

tip of the finger during that time. In spite of this, his epiphyseal development is delayed. Apparently, Joan got her growth earlier, and her epiphyses matured earlier. John's growth and epiphyseal union have both been delayed.

At the age of 18½ years, x ray films of John showed no change in the cranial vault or in the sella. The mandible

FIGURE 1. Photographs of the Twins.

*The one on the left was taken when they were eight years old; that on the right, when they were fourteen*

langes are closed and the others maturing, in other words, there is a difference of 2 or 3 years in bone age.

At the age of 17 years, the twins were x-rayed again; the reports were as follows:

Re-examination of John's skull shows a smooth vault, with no localized changes and no general signs of pressure; the sella turcica remains normal. Re-examination of the right hand and wrist shows all epiphyses open, with not even the changes of maturation (Fig. 2). The findings indicate a definite delay in epiphyseal union.

Re-examination of Joan's skull shows the sella to be normal, with no signs of intracranial pressure and no localized lesions. Re-examination of the right hand and wrist shows all epiphyses closed (Fig. 2); the bones appear normally developed.

Comparing the films of the twins at the age of 14 years and those at the age of 17 years, there has been no appreciable growth of the skull in either case. Comparing the hands, there has been no growth of Joan's bones, but John's have definitely grown, being 1 cm. longer from the base of the third metacarpal to the

appeared slightly larger and heavier, and the second molars had erupted since the examination 18 months previously. The right hand and wrist showed only slight changes, indicating beginning maturation of the epiphyses, particularly at the proximal end of the proximal phalanx of the middle finger. All the epiphyses were still open, and growth had not yet ceased.

All the films were interpreted by Dr. M. C. Sosman.

### Discussion

These twins are of interest because one twin developed diabetes insipidus at the age of five and a half years and subsequently had a retarded growth and development. In contrast, the other twin grew and matured normally. The x-ray findings are of interest because the twin with diabetes insipidus had a smaller skull than his twin sister and also because all the epiphyses of the right hand and wrist were open at the age of eighteen and a half years, whereas his twin sister's epiph-

yses were closed at seventeen years. The findings indicated a definite delay in epiphyseal union in the twin with diabetes insipidus.

Patients with diabetes insipidus do not necessarily have a retarded growth and development, although some do. With such a striking differ-

betes insipidus occurred among them. In none of these cases were there twins.

#### SUMMARY

This report presents a study of a pair of eighteen-year-old nonidentical twins, one of whom

FIGURE 2. X-ray Films of the Right Hand of Each Twin at the Age of Seventeen Years.

*At the left, the film of the normal twin's hand is shown; at the right, that of the twin with diabetes insipidus, in which the epiphyses are open.*

ence in the progress of growth of these twins, it appears that a disturbance in the anterior pituitary gland of the twin with diabetes insipidus interfered with his growth and bony development.

In the literature, I have been unable to find any reference to the occurrence of diabetes insipidus in one or both twins. Weil<sup>1</sup> and his son<sup>2</sup> discussed the inherited tendencies or the familial characteristics of diabetes insipidus. They described in detail the 220 members of five generations of one family, headed by a man with diabetes insipidus, and reported that 35 cases of dia-

developed diabetes insipidus at the age of five and a half years. The twin with diabetes insipidus had retarded growth and development. The normal twin grew and matured normally.

The x-ray findings of the right hand and wrist were interesting because there was a definite delay in the epiphyseal union in the twin with diabetes insipidus.

## MEDICAL PROGRESS

### INDUSTRIAL HYGIENE

SHERMAN S. PINTO, MD,\* AND MANFRED BOWDITCH†

BOSTON

ANY branch of medicine may be broadened along two main lines: through an increase in scientific knowledge, such as discoveries in individual laboratories or clinics, and through widespread application of new discoveries, that is, through popularization. Both lines are of definite importance, since only the widespread application of new discoveries can justify the great expenditures of time and money necessary to research.

Industrial hygiene is concerned with the preservation and improvement of the health of workers. In this field, many significant advances have been made in the last few years, but not until very recently has any emphasis been placed on the application of these advances to as large a proportion of the industrial population as possible. Before 1936, there were only half a dozen state departments conducting industrial-hygiene activities in even a limited way.<sup>1</sup> Under the stimulus of funds supplied wholly or in part by the federal government, thirty two states and four cities now support industrial hygiene units,<sup>2</sup> and these states have a working population of forty million people. Thus, the mechanism is being rapidly perfected for bringing about widespread application of the knowledge of industrial hygiene.

It is through the general practitioner that the new discoveries of industrial hygiene must be brought to the worker, for only 15 per cent of workers in this country have the advantage of full time medical services during working hours.<sup>3</sup> Industrial absenteeism due to injury and sickness can be greatly influenced by the skill with which the private practitioner handles these cases,<sup>4</sup> and on him rests the responsibility for recognizing early, and treating correctly, disorders caused by industrial operations and environment. He must also have the preventive side of the picture in mind and must seek to determine whether measures may be taken to reduce the frequency of the illnesses being treated. It has been said that any community may decide for itself whether or not it wishes to suffer from diphtheria. Just as truly may it be said that any industry may decide

whether or not health is to be threatened by employment in its plants.

Both state and federal industrial-hygiene units are set up to study problems and furnish advice along medical, chemical and engineering lines. In addition, most state medical societies have a committee on industrial health or the equivalent. It is to agencies such as these that the private practitioner should turn when new problems in the field of industrial hygiene arise.

#### DERMATITIS

Skin irritation from substances used in industry present numerically the greatest number of industrially induced cases of disease. As industry develops, so do new methods and chemicals that frequently cause skin irritation, even though the more serious toxic manifestations are not found. Sterner<sup>5</sup> states that, in one company alone, from 10,000 to 12,000 different chemicals are employed, and that between one and several hundred employees may be exposed to any of them.

Among the commoner causes of dermatitis in industry are the cutting oils. These oils apparently cause dermatitis by blocking the sebaceous glands.<sup>6</sup> Because of this mechanical blocking, the natural oily secretions of the skin are held back, accumulate, harden, and eventually cause enough irritation to produce a dermatitis. Infection also plays a part, but is believed to be produced by organisms normally present on the skin.<sup>7</sup> For cleansing the oil from the skin, a mixture of pure liquid soap and sawdust in equal parts has been recommended. Klauer et al.<sup>8</sup> have suggested the use of a mixture containing 45 per cent each of sulfonated neat's foot oil and light liquid petrolatum and 10 per cent of a 25 per cent aqueous solution of gelatin. To one part by weight of the oil mixture are added one and a half parts of white granulated corn meal. Chlorobutanol (0.5 per cent) may be added to prevent mold or bacterial growth. This mixture of corn meal oil replaces harsh abrasive soaps and brushes or rags in the daily cleansing of the skin. Klauer's article contains valuable formulas for other skin-cleansing detergents and skin protective creams that may be satisfactorily used in numerous industrial conditions.

All articles in this series will be published in book form the current volume is *Medical Progress Annual, 1940* (Springfield Illinois: Charles C. Thomas & Company, 1941, \$4.00).

\*Physician, Massachusetts Division of Occupational Hygiene.  
†Director, Massachusetts Division of Occupational Hygiene.

Other industrial causes of dermatitis are too numerous to list, but attention should be called to the chlorinated naphthalenes, chlorinated hydrocarbons<sup>9</sup> and the general class of substances known as resins.<sup>10</sup> The use of these materials is increasing, but an accurate diagnosis can be made only by careful search into the occupational history of the patient.

From the wide variety of industrial substances known to cause dermatitis, it is apparent that they may act in several ways. The dermatitis may result from primary irritation or mechanical action, or may be an allergic response. At one time, it was thought that hypersensitive persons could be determined by pre-employment patch testing. Experience has shown this method to be impractical, since a large proportion of industrial allergic sensitivity is acquired only after employment and contact with the offending substance for weeks or months.

An infectious disease of occupational origin that first manifests itself by the appearance of a typical skin lesion is anthrax. The incidence of this condition is increasing, and fatal results can be prevented only by early diagnosis and treatment. The use of serum is still the method of choice for combating infection and toxemia.<sup>11</sup>

#### BENZOL

Because of its physical and chemical characteristics, benzol is one of the best solvents from the industrial point of view. From the standpoint of health, however, it is one of the most dangerous to use, since it is likely to cause disorders of the blood-forming organs. Recent studies by several investigators have done much to show how protean are the early manifestations of the action of small amounts of benzol on the body. Most industrial workers inhale the fumes of benzol, and are chronically poisoned by this method, rather than through skin absorption. Evidence of benzol exposure and absorption may be found by a change of the inorganic-total sulfate ratio of the urine.<sup>12, 13</sup> Bowditch and Elkins,<sup>14</sup> in studying this ratio among workers exposed to benzol, found that it was lowered after exposure to benzol vapors. Although this test alone does not indicate benzol poisoning, it is a good measure of the amount of benzol absorption following exposure.

The initial blood changes in benzol poisoning are of the utmost significance, since it is only by early detection of this condition that extensive damage can be prevented. Hunter<sup>15</sup> found many types of blood changes resulting from benzol—polycythemia, anemia, leukocytosis, leukopenia,

leukemoid blood conditions, eosinophilia, megalocytosis and microcytosis. He states that the early diagnosis of poisoning depends on an evaluation of the complete blood picture rather than on the existence of a leukopenia. Erf and Rhoads<sup>16</sup> studied the blood picture in early benzol poisoning and also found an extremely varied, but abnormal, blood picture. They noted anemia, leukopenia, thrombocytopenia and elevation of reticulocyte counts as commonly occurring changes. Greenburg et al.,<sup>17</sup> in a study of 332 workers exposed to benzol, found the following significant abnormalities: an anemia; an increase in the mean corpuscular volume of the red cells; and a reduction in blood platelets. These workers state that too great reliance should not be placed on the leukocyte count *alone* as a rapid means of detecting cases of benzene poisoning. In their experience, leukopenia was found more frequently in severe than in early cases.

Goldwater<sup>18</sup> decided from studying a large group of patients exposed to benzol vapors that the abnormalities most frequently observed were anemia, macrocytosis and thrombocytopenia. In a later study of recovery from chronic, mild benzol poisoning, he<sup>19</sup> found that damage to the blood-forming organs may persist for at least two years following cessation of exposure, although the majority of people recover within fourteen months.

From these and other studies, authorities have attempted to set a safe limit for the amount of benzol that may be in the air breathed by workmen. One group<sup>20</sup> has suggested 75 parts per million as a safe and attainable figure, whereas another observer<sup>15</sup> rather pessimistically says, "It is doubtful whether any concentration of benzene greater than zero is safe over a long period of time."

With these new methods for diagnosing benzol poisoning available, it is incumbent on all physicians treating workers who might possibly be exposed to benzol vapors to study such patients from this point of view. If the old-time concept of leukopenia is thought of as the sole diagnostic sign of benzol poisoning, most of the chronic, and sometimes fatal, cases of benzol poisoning will be overlooked.

#### CARBON DISULFIDE

Hamilton,<sup>21</sup> in reviewing carbon disulfide poisoning, points out that diagnosis is difficult, since so many of the symptoms are subjective. The mental symptoms, which are most striking, range from simple irritability and depression to manic-depressive insanity. Other symptoms are neuritis,

ocular manifestations,—such as enlargement of the blind spot and diminution of the corneal reflex,—dermatitis and gastrointestinal disturbances. From the laboratory side of the picture, diagnosis may be made more certain by analyzing biologic fluids for their carbon disulfide content according to the method of McKee.<sup>22</sup> Since this falls rapidly after exposure ceases, analyses must be made during or shortly after the period of exposure.

### LEAD

Progress in the diagnosis of lead poisoning has been made primarily in the laboratory. More sensitive methods for the analysis of urine and blood are a great aid in confirming or refuting a tentative diagnosis of lead poisoning. The most important advances in technic have been made by Willoughby and Wilkins,<sup>23</sup> Ross and Lucas<sup>24</sup> and Kehoe et al.<sup>25</sup> Parenthetically, it may be stated that the accurate determination of lead in blood and urine is one to be undertaken only by a skilled chemist. A number of state occupational hygiene agencies are capable of making these tests, and the practitioner will do well to get in touch with such units when he desires to have the tests made.

### MERCURY

One of the recent bright spots in the prevention of disease concerns the use of mercury in the fur felt hat industry. 'Mad as a hatter' is a phrase that has long been a byword in the English language; translated into terms of industrial medicine, it means simply an occupational mercury poisoning such as the felt hat maker has frequently acquired. Mercury is used for 'carrotting' fur, a process by which fur is so changed that it may be made into felt. Through the combined efforts of industrialists, laborers, physicians and governmental agencies, it was decided that only nonmercury-carroted fur could be used for felt hat making in the United States after December 1, 1941.<sup>26, 27</sup> This splendid step forward, possible only through the co-operation of all interested groups, is an example of how such problems might well be attacked. When the prevalence of mercury poisoning in the fur felt hat industry was recognized, an effort was made to find substitutes for the process in which mercury was used. After such substitutes had been found, industry willingly co-operated to replace the highly dangerous process with a far safer one.<sup>28</sup>

### CONCENTRATION OF CHEMICALS IN AIR

To clarify the question of air concentrations of toxic substances that are considered comparable with safe working conditions, Table I is given.

In it, the air concentration of the industrial substance is expressed as parts per million (ppm) unless otherwise specified. This list is abstracted.

TABLE I Suggested Maximum Safe Concentration of Certain Industrial Chemicals

GAS OR VAPOR	CONCENTRATION ppm	GAS OR VAPOR	CONCENTRATION ppm
Ammonia	100	Lead	0.15*
Amyl acetate	400	Mercury	0.10*
Acetone	1	Methanol	200
Benzene (benzol)	75	Nitrobenzene	5
Carbon disulfide	15	Nitrogen oxides	10
Carbon monoxide	100	Ozone	1
Carbon tetrachloride	100	Phosgene	1
Chlorosulphatene	1 to 5*	Phosphine	2
Ether	400	Sulfur dioxide	10
Formaldehyde	20	Tetrachlorethane	10
Gasoline	1000	Toluene	200
Hydrogen cyanide	20	Trichlorethylene	200
Hydrogen sulfide	20	Zinc oxide	15*

\*Milli grams per cubic meter

from that recently published by a group conversant with this problem.<sup>29</sup>

### THE FUTURE

Each new chemical introduced to industry is a potential health hazard until proved otherwise. Under the present stimulus of national defense, the use of certain materials has increased tremendously. Although most of these are chemicals with which the practitioner is more or less familiar, the industry of war utilizes some materials peculiar to itself. The following are mentioned to warn how and where danger may be expected.

Tetryl is an explosive that is notorious for the amount of dermatitis it causes among those handling it. Silver<sup>29</sup> has reviewed the subject thoroughly with reference to workers in England affected during the present war.

Trinitrotoluene (TNT) causes both dermatitis and general systemic disease. The earliest sign of systemic poisoning is a mild cyanosis. Moderate exposure frequently causes anemia, whereas severe poisoning may cause acute yellow atrophy of the liver or an aplastic anemia.<sup>30, 31</sup>

Radium is being used in large amounts to produce luminescent paints. As these paints are applied to such objects as airplane instrument dials, it is readily seen that the quantity used will steadily become larger. Radium poisoning, with resultant bone tumors, is well known, but if radium is handled according to specifications recently issued by the Bureau of Standards, such tragic accidents should not occur.<sup>32</sup>

recorded, so that I assume none were done. No mention is made of the white-centered petechiae that are found in endocarditis of the verrucous type. There are many pathologists who believe that no clear-cut findings are available to differentiate lupus and Libman-Sachs syndromes except greater than average involvement of the endothelium. This is especially true of cardiac valvular disturbance.

Without any evidence for the diagnosis except the statistics that almost 50 per cent of cases of disseminated lupus have coarse verrucous endocarditis, it seems best to ignore this pitfall. My diagnoses, therefore, are disseminated lupus erythematosus, healed tuberculous adenitis and terminal pneumonia. It is possible that the arthritis was rheumatoid in type and that there was an incidental pyelonephritis.

#### CLINICAL DIAGNOSES

Lupus erythematosus disseminatus.  
Arthritis deformans.  
Tuberculosis of lymph nodes.

#### DR. WARTHIN'S DIAGNOSES

Lupus erythematosus disseminatus.  
Tuberculous adenitis, healed.  
Pneumonia, terminal.  
Arthritis, rheumatoid?  
Pyelonephritis?

#### ANATOMICAL DIAGNOSES

Acute disseminated lupus erythematosus.  
Polyserositis, chronic fibrous.  
Bronchopneumonia.  
Generalized lymphadenopathy.  
Tuberculosis of cervical lymph nodes.  
Rheumatoid arthritis of wrist and phalanges?

#### PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: This is one of the cases that discourage the morphologist. The immediate

cause of death was, of course, a terminal bronchopneumonia, but of the fundamental underlying disease there was extremely little visual evidence. The skin rash was still present but was naturally much less vivid than it had been during life. Slight fibrous adhesions were found in both pleural cavities, in the pericardium and between the diaphragm and the upper surface of the liver, to indicate that the patient had had at one time a polyserositis. There was no endocarditis, and all the visceral organs except the lungs were entirely normal. A few old calcified lymph nodes were found in the lower cervical region, but there was no evidence of active tuberculosis. One evidence of probable activity besides the skin rash was the finding of a generalized lymph adenopathy. The retroperitoneal lymph nodes, for instance, were more or less uniformly about 1 cm. in diameter, pink, soft and edematous.

Microscopic examination gave us little more information. The lymph nodes did show congestion and necrosis of the germinal centers, a very constant finding in acute disseminated lupus. A few lymphocytes were found in the pericardium and pleura. The cervical lymph nodes showed completely inactive tuberculosis. Even the kidneys proved entirely normal — not only were there no wire-loop lesions, but even focal glomerulonephritis, which in our experience is frequent in this disease, was lacking. The most important function of the pathologist in such a case is to rule out other disease entities. That we could easily do, and hence there can be no doubt that Dr. Warthin's diagnosis of acute disseminated lupus was correct. It is quite unusual in lupus to see permanent changes in the involved joints. Unfortunately, we did not have permission to examine the joints of the hands in this patient, and we therefore cannot rule out the possibility of a complicating rheumatoid arthritis.

ocular manifestations,—such as enlargement of the blind spot and diminution of the corneal reflex,—dermatitis and gastrointestinal disturbances. From the laboratory side of the picture, diagnosis may be made more certain by analyzing biologic fluids for their carbon disulfide content according to the method of McKee.<sup>22</sup> Since this falls rapidly after exposure ceases, analyses must be made during or shortly after the period of exposure.

# CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED  
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

## CASE 27501

### PRESENTATION OF CASE

A thirty-six-year-old factory worker was admitted to the hospital because of pain in the right shoulder.

He was well until the insidious onset of intermittent dull aching pain in the right shoulder, about six months before entry. After two months, he was aware of swelling of the shoulder and limitation of motion upward and backward. The pain gradually increased in intensity, became constant, and radiated to the tips of the fingers of the right hand. In the few weeks preceding entry, the pain was so severe that the patient was scarcely able to sleep. There was a loss of 6 pounds in weight. A physician, consulted early during the illness, told the patient that he had "rheumatism." Four days before entry, this physician took a roentgenogram of the shoulder and, on the basis of the film, referred the patient to the hospital.

The patient's mother had died of carcinoma of the stomach. There was no other family history of cancer. The patient had always been in good health, except for a railway accident twenty-six years before entry in which part of his left leg was avulsed, necessitating skin-graft treatment.

On admission, the patient appeared thin, with obvious swelling of the upper right arm and shoulder. This swelling consisted of a peach-sized mass, apparently situated deeply between the neck of the humerus, the acromion and the distal end of the clavicle. A stony-hard small mass and a soft small mass, both freely movable, were palpable in the position of lymph nodes of the right axilla. The arm was held in 40° abduction, at rest, and could be abducted to only 90°. External and internal rotation were likewise limited, and the arm could not be placed behind the back. The chest was clear, and physical examination was otherwise negative, except for signs of old injury to the left lower leg, which was bowed anteriorly and covered by tense, scaling, atrophic skin.

The temperature, pulse and respirations were normal. The blood pressure was 138 systolic, 80 diastolic.

Examination of the blood showed a white-cell count of 11,100 and 95 per cent hemoglobin. The blood calcium was 11.3 mg. and the phosphorus 3.4 mg. per 100 cc., and the phosphatase was 16.3 Bodansky units. The urine was normal.

A roentgenogram of the right shoulder showed destruction within the upper end of the shaft of the humerus, with extensive condensation of the bone and some new-bone formation. Discrete areas of calcification were evident, high in the axilla. Roentgenograms of the chest and abdomen were negative.

On the fifth hospital day, an operation was performed.

### DIFFERENTIAL DIAGNOSIS

DR. CLIFFORD C. FRANSEEN: This history could fit in with a number of lesions, and we shall have to rely heavily on the x-ray findings for our diagnosis.

DR. JAMES R. LINGLEY: The films show this extensive lesion involving the proximal extremity of the humerus, characterized by bone destruction and a large amount of new-bone formation. The new bone extends out into the soft tissue for a considerable distance, and there are separate discrete areas of calcification high up in the axilla. The chest shows no evidence of disease.

DR. FRANSEEN: I was inclined, before I saw the x-ray films, to discount the small calcified mass in the axilla, which was described as small and stony hard, as incidental, but a view of the films suggests that the mass is definitely related to the lesion in the shoulder. It is not infrequent in cancer of the breast to see calcified lymph nodes in the axilla or supraclavicular region, which often make it difficult to decide whether metastases are present. Sometimes, for example, the presence of calcified supraclavicular lymph nodes may mislead one in deciding whether a radical mastectomy should be done.

I see no alternative but to go through the usual routine of differential diagnosis. When it is difficult to make a diagnosis, it is customary to deplore the lack of further information. The blood serologic findings in this case are not reported. Before seeing the films, I had syphilis in mind, perhaps because I was sensitized to the diagnosis by a recent case in a man of this age who also had involvement of the upper end of the humerus. There is obviously a large soft-tissue mass suggestive of tumor, and although syphilis can simulate any lesion of bone, certainly there is nothing about this case that, on first glance, suggests syphilis to me. The blood chemical f

a little puzzling, and I wonder if they had any relation to this lesion. There is a good deal of calcification for some reason, and it may have been that that amount of calcification or mobilization of calcium was responsible for the slightly elevated blood calcium. In Aub's<sup>1</sup> series of calcium determinations, the average normal was 10.8 per 100 cc. (Fiske method), and in only 3 cases, among several hundred examined, it ranged from 11.0 to 11.3 mg. It is difficult to know why it should be so high in this case. Of course in the last

We have already ruled out syphilis, but the elevated phosphatase reminded me that we had one patient with an elevated phosphatase apparently caused by antisyphilitic treatment. When patients receive Coley's toxins for tumors of the bone, toxic hepatitis, in addition to some elevation of the phosphatase, results. If the patient had received either of these treatments, it could possibly be the explanation here.

The picture does not look at all characteristic of osteomyelitis to me, with so much new-bone

FIGURE 1. *Sclerosing Osteogenic Sarcoma of the Head of the Humerus, with Two of the Ossified Lymph-Node Metastases.*

two or three years, a good many cases of various bone lesions have been reported with elevated calcium. Multiple myeloma is particularly notorious in this respect, but in most of these cases the phosphorus is more nearly normal. Consequently, on the basis of these blood chemical findings alone, I do not believe that we can make any flat-footed statement. The phosphatase of 16.3 Bodansky units, of course, is elevated, perhaps to four times normal, and with the amount of new-bone formation here, this value is perfectly compatible with the observations in the x-ray study concerning the presence of ossification.

Tuberculosis always comes to mind. My experience with tuberculosis is rather limited. The patient was rather old, since tuberculosis is usually a juvenile disease. It can occur in this location, but there is a large soft-tissue tumor mass in conjunction with the lesion. I do not consider tuberculosis very seriously for these reasons.

formation in this region. Obviously, there is a large mass, which does not seem to be inflammatory.

Granulomas of bone do not have to be considered seriously. They are almost purely destructive, and so far as I know, the end of a long bone is an unusual site for them.

Hyperparathyroidism is suggested only because of the blood chemical findings, but certainly the x-ray picture does not suggest anything I am familiar with in this disease.

Lymphoma has been reported to simulate various types of bone tumors, sometimes with considerable production of new bone. There is nothing else about the patient to suggest the diagnosis. He lost 6 pounds in weight, and there are other things suggesting that there might have been some underlying systemic condition, but certainly it was not characteristic of the usual picture of lymphoma of bone, which more commonly occurs

in the late stages when it is evident elsewhere in the body.

Ewing's tumor could occur in this man. He was at the upper limits, perhaps, of the age when it is most common, and there was an unusual amount of new-bone formation. The lesion was near the head of the bone, which is a less likely site.

The presence of so much calcification in the tissues, and even in the lymph nodes, presumably, disturbs me a good deal. I know of no case of osteogenic sarcoma in which there has been calcification in the regional nodes themselves. Calcification occurs in the lungs in metastases from osteogenic sarcoma, and I have done phosphatase determinations on the tissues in these nodules and found them as high as that in the original tumor. I remember a case at the Palmer Memorial Hospital in which the lymph nodes suggested disease in the x-ray picture, but at the time of operation these nodes were removed and showed no calcification by pathological examination.

I have never seen any metastatic lesions that had laid down so much new bone, and the man is also relatively young. There is nothing about the picture to suggest Paget's disease. The other thing one would have to think of with so much calcification around the joint is a Charcot joint or, possibly, the condition that resembles it on x-ray examination and is secondary to syringomyelia. There is no suggestion here of such disorganization of the structures of the bone. We have no serologic evidence of syphilis, so far as Charcot's joint goes, but the lesion could occur without it from syringomyelia.

I am left with nothing but low grade osteogenic sarcoma to consider. I have seen cases of osteogenic sarcoma with a good deal of calcification in the surrounding tissues. I am at a loss to explain the case on any other basis with the evidence at hand. A conclusive diagnosis would depend on the results of the biopsy examination.

DR. LINGLEY. The roentgen appearance of the lesion in the humerus is typical of osteogenic sarcoma. The case is very interesting to me because I have never seen calcified osteogenic-sarcoma metastases in lymph nodes. I have seen them in the lungs, but not in the regional lymph nodes. It appears that such a metastasis occurred in this case.

DR. GRANTLEY W. TAYLOR. We were very much interested in this problem in the Tumor Clinic, and we believed that we should confirm the diagnosis by biopsy of one of the nodes before proceeding to therapy. We were able to confirm

the diagnosis of osteogenic sarcoma from one of the lymph nodes. The case is uniquely interesting because lymph node metastases from osteogenic sarcoma are very rare. In any event, Dr. Shields Warren,<sup>2</sup> when he reported metastases from various types of sarcomas in his series, had only one case of lymph node metastasis from osteogenic sarcoma. There are a few others. Dr. Thomas J. Anglem had a case similar to this in which actual bone formation was taking place in the regional lymph nodes; but such cases must be extremely rare, since both lymph node involvement and calcification are rather unusual in metastases of osteogenic sarcoma. Ossifying metastasis even in the lungs is rare enough to excite comment, and here we have the two unusual features combined in one case.

DR. FRANSEEN. I went over all the bone tumors at the Radiumhemmet in Sweden to see if I could find any case with metastases to the nodes, but I could not find one case.

#### CLINICAL DIAGNOSIS

Osteogenic sarcoma of humerus, with metastases to axillary lymph nodes.

#### DR. FRANSEEN'S DIAGNOSIS

Osteogenic sarcoma of humerus

#### ANATOMICAL DIAGNOSIS

Osteogenic sarcoma of humerus, with ossifying metastases in the regional nodes.

#### PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY. I presented this case before the American College of Surgeons when Dr. Murray Copeland was present, and he said he had seen a number of cases of osteogenic sarcoma with metastases to nodes; in fact, he put the figure as high as 5 to 7 per cent, which was ever so much higher than I should have supposed. I suspect that the figures were probably compiled from autopsy material rather than from clinical examination.

This patient had a number of calcified nodes in the axilla that showed extensive ossification. The primary tumor was a very characteristic osteogenic sarcoma arising in all probability in the diaphysis just next to the epiphyseal line, but it had crossed it and invaded the head extensively. Microscopically, it is a relatively slowly growing, sclerosing tumor, with marked bone formation. The picture in the lymph nodes is indistinguishable from that in the primary tumor.

DR. TAYLOR. Is there definite evidence that these lymph nodes had been invaded by the disease?

DR. MALLORY: In one, in particular, we could see a central mass of bone completely surrounded by lymphoid tissue.

#### CASE 27502

##### PRESENTATION OF CASE

A twenty-six-year-old single woman entered the hospital complaining of a rash on the skin.

Seven weeks before entry, the patient developed a chill and some fever. She continued to have fever and at least one chill each day for the following week. During the second week of her illness, the chills were less frequent, but the fever persisted. Five weeks before entry, a red spot appeared on the right cheek. This continued gradually to spread over both cheeks, nose, neck, upper part of chest, arms and finally to the legs. The patient soon noticed that her fingers were also very red and sore. Three weeks before admission, she began to have a considerable amount of putrid, often blood-stained discharge from her nose. During this period, she went downhill steadily, slept poorly, and had a very poor appetite.

Her father had died of influenzal pneumonia at the age of thirty-nine. Her mother, two brothers and one sister were living and well. There was no history of any chronic disease in the family.

Ten years before entry, the patient was admitted to this hospital for enlarged cervical lymph nodes. A biopsy was done, and a diagnosis of tuberculous adenitis was made. After leaving the hospital, she went to a sanatorium, where she gained 52 pounds in thirteen months. She remained at home for about a year and a half and then returned to the sanatorium because her hands had begun to swell and had become painful. She was finally discharged after three years and was well at home for about two years. During this period, her hands became deformed.

Physical examination showed a poorly developed and very poorly nourished woman, lying quietly in bed, who appeared acutely ill. The skin over the nose and cheeks was very red and slightly indurated. Smaller bright-red, smooth areas were found on the neck and upper part of the sternum. There were similar lesions, about 5 cm. in extent, on the upper part of the back at about the seventh to ninth dorsal spines. The skin of the arms, particularly the extensor surfaces, had many of these flat, red, slightly indurated lesions, which had coalesced, giving an almost complete involve-

ment of the skin. The fingertips were red, tender and in some places cracked open. The legs had more widely scattered lesions. There were a few excoriations over the abdomen. The mucous membrane of the mouth and nose showed a few scattered hemorrhagic spots. The breath was very foul. There was a foul-smelling, abundant, mucopurulent hemorrhagic discharge from the nose. The teeth were in fair condition. The gums were dark red and hemorrhagic. All the cervical, axillary and inguinal lymph nodes were enlarged, some up to 1 or 2 cm. in diameter; they were hard and slightly tender. Both hands were deformed by an arthritic process and could not be opened or closed; the phalangeal joints were enlarged.

The temperature was 102.1°F., the pulse 116, and the respirations 26.

Examination of the urine showed a specific gravity of 1.008 and a sediment containing 10 to 12 white blood cells in small clumps, many cellular and granular casts and numerous bacilli per high-power field. Examination of the blood showed a red-cell count of 3,720,000 with a hemoglobin of 70 per cent, and a white-cell count of 3900 with 70 per cent polymorphonuclears. A blood Hinton reaction was negative. The bleeding time was 3½ minutes. The nonprotein nitrogen was 21 mg., the cholesterol 83 mg. and the serum protein 7.7 gm. per 100 cc.

A chest film showed marked calcification of all the lymph nodes in the neck. This calcification lay over both apices, so that it was difficult to decide whether the process was in the lung fields. There was no beading or mottling suggestive of tuberculous activity.

The temperature ranged between 99 and 102°F. The joint pains were quite severe, and the patient was given 75 gr. of sodium salicylate daily. She developed edema of the face and complained of a sore throat. Salicylates were stopped because of marked vomiting. On the thirteenth day, she became comatose, and rales were heard in the chest. She had more bleeding from the mouth and died that day.

#### DIFFERENTIAL DIAGNOSIS

DR. THOMAS A. WARTHIN: Certainly, the acute onset of septic constitutional symptoms, followed by the appearance of a widely disseminated bright-red rash, narrows the differential diagnosis to a small group of disturbances. Typhoid fever can be dismissed immediately because of the character of the skin lesions. So also can the septicemia group, including subacute bacterial endocarditis, meningococcemia, and staphylococcal, colon bacillus and streptococcal infections. Erythema multi-

forme, associated perhaps with severe acute rheumatic fever, would undoubtedly have exhibited a number of typical vesicular lesions of the iris. Undulant fever, when associated with skin manifestations, presents a more discrete papular eruption. The rickettsial diseases are of shorter duration than the infection in this case, and their petechial and hemorrhagic rashes do not coalesce so strikingly. I know of no fungous infection associated with skin eruptions in which papular or pustular lesions do not predominate. The negative blood Hinton reaction completes rejection of syphilis as a possibility.

When the patient was sixteen, cervical tuberculous adenitis was proved by biopsy, and the patient was apparently successfully treated for over a year at a sanatorium. However, she did return one and a half years later for treatment of painful swelling of her hands, and remained in the institution for three years. During this time, her hands became deformed. Bilateral deforming involvement of the hands due to tuberculous dactylitis appears mainly in infants. Sarcoid does not fit into the picture of the terminal illness and in addition, that diagnosis would force us to conclude that the lymph node biopsy had been incorrectly interpreted. We are told that this deformity was due to an arthritic process, which makes scleroderma unlikely. Furthermore the patient was in a younger age group than most patients with scleroderma, and no mention is made of associated Rynaud's phenomena.

Could military tuberculosis and tuberculosis cutis explain the final illness? I believe not since there is no evidence of military tuberculosis in the chest film. In addition, lupus vulgaris sclerosis erythematosus, which closely simulates lupus erythematosus, is accompanied by marked rather than slightly indurated skin lesions. This results in considerable scarring in the center of the lesions which this case lacked. Ulceration is very prone to occur in tuberculosis cutis of this type.

For final consideration, we have the group of closely related diseases with vascular disturbances, namely, disseminated lupus erythematosus, Libman-Sachs syndrome and periarteritis nodosa. Scleroderma and dermatomyositis also have more or less generalized vascular lesions, but they clinically present quite different pictures, atrophy of the skin and swelling of the muscles predominating, respectively. Periarteritis nodosa commonly affects males, and the presenting symptomatology is apt to be related to the renal, abdominal, neuro-muscular, cardiac or bronchial systems rather than to the skin. Cutaneous lesions of many types besides nodules along superficial arteries have

been described. Leukocytosis, with or without eosinophilia, rather than leukopenia, characteristically occurs in periarteritis.

If one lists the characteristics of this case, one is immediately struck by consistent similarities with disseminated lupus. The patient was a woman, and was in the second to fourth decades of life. She suffered from the frequently present tuberculous adenitis, which has clouded the theories of etiology of the disease. The onset of the final illness was fulminating, with the chills and fever that may occur in a severe case. Chills are not characteristic, but may be present, it is possible that a pyelitis immediately preceded the lupus. The rash appeared after the onset, as it frequently does. Unfortunately, we are not told whether exposure to sunlight precipitated or intensified the rash. The rash was typical in that it first appeared on the face, with gradual spread to the neck, chest, arms and, finally, the legs. It was characteristically bright red and slightly indurated, with a tendency to coalesce. It involved the fingers, and as frequently occurs, the mucous membranes of the hands were involved, but had been so for several years. It is possible that the lesions occurred during an early phase of the disease, in a subacute form that became quiescent, only to flare up acutely seven weeks before the final entry. Such remissions occur frequently in periarteritis nodosa, and less commonly in lupus. Her long stay in the sanatorium stimulates this speculation, and without it one would be forced to add another diagnosis, that of rheumatoid arthritis. As described, the hands could have been rheumatoid, but it is surprising that no other joints were affected. We are told nothing about eyegrounds, blood pressure, lungs or abdomen, and I consequently assume that they were normal, although the involvement of serous surfaces is common. Nausea, vomiting, edema of the face and joint pain are frequently observed.

The laboratory studies revealed the numerous casts so frequently seen in disseminated lupus, and evidence of some bacilluria and pus. These bacilli were probably secondary invaders, although it is possible that a pyelitis precipitated the final illness. However, the kidneys were not severely involved, as indicated by the nonprotein nitrogen level. Usually, there is some azotemia in lupus. The blood count reveals bone marrow depression by the typical anemia and leukopenia. The chest x-ray film helps rule out a military tuberculosis. The final coma, in addition to the rales, is in keeping with terminal lupus. Without mention of heart murmurs, it is difficult to consider the Libman-Sachs syndrome. No blood cultures are

recorded, so that I assume none were done. No mention is made of the white-centered petechiae that are found in endocarditis of the verrucous type. There are many pathologists who believe that no clear-cut findings are available to differentiate lupus and Libman-Sachs syndromes except greater than average involvement of the endothelium. This is especially true of cardiac valvular disturbance.

Without any evidence for the diagnosis except the statistics that almost 50 per cent of cases of disseminated lupus have coarse verrucous endocarditis, it seems best to ignore this pitfall. My diagnoses, therefore, are disseminated lupus erythematosus, healed tuberculous adenitis and terminal pneumonia. It is possible that the arthritis was rheumatoid in type and that there was an incidental pyelonephritis.

#### CLINICAL DIAGNOSES

Lupus erythematosus disseminatus.  
Arthritis deformans.  
Tuberculosis of lymph nodes.

#### DR. WARTHIN'S DIAGNOSES

Lupus erythematosus disseminatus.  
Tuberculous adenitis, healed.  
Pneumonia, terminal.  
Arthritis, rheumatoid?  
Pyelonephritis?

#### ANATOMICAL DIAGNOSES

Acute disseminated lupus erythematosus.  
Polyserositis, chronic fibrous.  
Bronchopneumonia.  
Generalized lymphadenopathy.  
Tuberculosis of cervical lymph nodes.  
Rheumatoid arthritis of wrist and phalanges?

#### PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: This is one of the cases that discourage the morphologist. The immediate

cause of death was, of course, a terminal bronchopneumonia, but of the fundamental underlying disease there was extremely little visual evidence. The skin rash was still present but was naturally much less vivid than it had been during life. Slight fibrous adhesions were found in both pleural cavities, in the pericardium and between the diaphragm and the upper surface of the liver, to indicate that the patient had had at one time a polyserositis. There was no endocarditis, and all the visceral organs except the lungs were entirely normal. A few old calcified lymph nodes were found in the lower cervical region, but there was no evidence of active tuberculosis. One evidence of probable activity besides the skin rash was the finding of a generalized lymph adenopathy. The retroperitoneal lymph nodes, for instance, were more or less uniformly about 1 cm. in diameter, pink, soft and edematous.

Microscopic examination gave us little more information. The lymph nodes did show congestion and necrosis of the germinal centers, a very constant finding in acute disseminated lupus. A few lymphocytes were found in the pericardium and pleura. The cervical lymph nodes showed completely inactive tuberculosis. Even the kidneys proved entirely normal—not only were there no wire-loop lesions, but even focal glomerulonephritis, which in our experience is frequent in this disease, was lacking. The most important function of the pathologist in such a case is to rule out other disease entities. That we could easily do, and hence there can be no doubt that Dr. Warthin's diagnosis of acute disseminated lupus was correct. It is quite unusual in lupus to see permanent changes in the involved joints. Unfortunately, we did not have permission to examine the joints of the hands in this patient, and we therefore cannot rule out the possibility of a complicating rheumatoid arthritis.

## THE RELATION OF THE PRACTICING PHYSICIAN TO INDUSTRIAL MEDICINE

Two articles in this issue of the *Journal* call attention to the important role played by the practicing physician in industrial medicine. As Mr. Bloomfield, of the Division of Industrial Hygiene, United States Public Health Service, points out, the majority of industrial workers are not furnished with medical care by full-time or part-time plant physicians. Furthermore, the chief causes of disability are illnesses arising from nonindustrial diseases, which, in many cases, result from poor living conditions, improper diets and contagious diseases among the workers' families.

Because of the tremendous increase in industrial activity demanded by the defense program and because of the accompanying hazards occasioned

by the speeding-up of production and by the introduction of new methods, the demands for highly trained industrial physicians are much greater than they were several years ago, in spite of the fact that, during the last decade, there has been a gradually widening appreciation of the value of the application of the modern principles of industrial medicine, both to the worker and to the employer. As previously stated, however, the practicing physician is still chiefly concerned with the health of the employee, and it is on him that a great part of the success of the defense effort depends. He should be thoroughly familiar with the details of proper first-aid care, he should be cognizant of symptoms and signs of the commoner industrial intoxicants, he should not fail to consult with his state authorities concerning definite or doubtful cases of industrial disease, and he should give advice regarding improvement of living conditions and diet to the workers and their families. All in all, his responsibility is great and should not be shirked.

## BRUCELLOSIS AND PASTEURIZATION OF MILK

INVESTIGATORS of the problem of undulant fever or brucellosis claim that in various sections of the United States from 5 to 10 per cent of healthy adults give evidence—by positive agglutination or intradermal tests—of having been infected with *Brucella abortus* at one time or another. Dustin and Weyler<sup>1</sup> go so far as to claim that among 4000 patients seen in private practice in Providence, Rhode Island, about 10 per cent gave what they considered sufficient clinical and laboratory evidence to warrant a diagnosis of chronic brucellosis. Such data are difficult to correlate with the figures of the Bacteriological Laboratory, Massachusetts Department of Public Health,<sup>2</sup> which for 1940 show that only about 4 per cent of the serums from cases of suspected brucellosis gave positive agglutination reactions, and those of the Bacteriological Laboratory, Boston City Hospital,<sup>3</sup> which in the last two years list only one positive reaction among serums from approximately 400 cases of unexplained fever on admission. It seems

logical to conclude that either one or the other group of tests is at fault, or that the incidence of brucellosis in Massachusetts is exceptionally low. As a matter of fact, both factors probably play a role.

The so-called "slide technic" has been, and still is, the generally accepted method of testing serums for agglutinating antibodies against *Br. abortus*. The preparations are examined under the microscope, and spontaneous or nonspecific agglutination is apt to be interpreted as being due to the presence of antibodies. On the other hand, the laboratories of the Massachusetts Department of Public Health and the Boston City Hospital have adopted the so-called "tube technic," in which a living or killed suspension of organisms is added to tubes containing various dilutions of serum, and the results are read macroscopically or with a hand lens. Although the latter method is possibly somewhat less sensitive than the former, positive tests are significant—a fact that explains, at least to some extent, the discrepancy between the reported results.

Even if one assumes that agglutinating antibodies are present in 2 to 5 per cent of the serums from healthy adults in other sections of the country, the figures of 4 and 0.25 per cent for cases of suspected brucellosis or unexplained fever, respectively, in Massachusetts are remarkably low, and the only reasonable explanation is the fact that nearly 90 per cent of the milk consumed in Massachusetts is pasteurized. That only 4 of the 52 cases of brucellosis in 1940 occurred in twenty-four contiguous communities in Metropolitan Boston, which contain 40 per cent of the total population of the State and where pasteurization regulations are in effect, and that only 1 case occurred among some 85,000 patients at the Boston City Hospital, are facts that corroborate the evidence given elsewhere in this issue of the *Journal* concerning the effectiveness of pasteurization as a preventive measure against brucellosis.

Such evidence, together with the fact that pasteurization of milk is effective against contamina-

tion by tubercle bacilli, typhoid and paratyphoid bacilli and streptococci, offers a strong argument in favor of the nation-wide adoption of regulations requiring pasteurization. To permit the marketing of raw milk is to subject the inhabitants of any community to needless danger.

#### MEDICAL EPONYM

##### LITTEN'S SIGN

Professor Moritz Litten (1845-1907), of Berlin, reported "Ueber die normaliter bei jeder Respiration am Thorax sichtbaren Zwerchfellsbewegungen: Eine physiologisch-klinische Beobachtung [On the Movements of the Diaphragm Normally Visible on the Thorax with Each Respiration: A physiologicoclinical observation]" in the *Deutsche medizinische Wochenschrift* (18:273-275, 1892). A portion of the translation follows:

I have observed that it is possible to see the movements of the diaphragm . . . on the thorax in all healthy men. The phenomenon takes the form of a wave motion that, beginning on both sides at the height of the sixth intercostal space, travels downward with maximum inspiration in the form of a straight line or shallow furrow (which makes an acute angle with the ribs) over several intercostal spaces, at times as far as the costal margin. With expiration, it rises again over the same area.

A more detailed account of the phenomenon is given in the paper, "Das Zwerchfellphänomen und seine Bedeutung vom physiologischen und klinischen Standpunkte [The Diaphragm Phenomenon and Its Significance from the Physiological and Clinical Standpoint]," which appeared in the *Verhandlungen des Kongresses für innere Medizin* (13:309-319, 1895). A portion of the translation follows:

The patient to be studied is placed in a horizontal position . . . with his feet toward the window, while the examiner, standing three or four steps away with his back toward the window, observes him from an angle of about forty-five degrees. . . . We are convinced that in a dark room the phenomenon is visible only if a source of light is so placed that the beams strike the thorax from the direction of the feet at an acute angle with the thorax.

## FATAL HEMORRHAGE DURING LABOR

A thirty four year old para IX who had had no prenatal care entered the hospital in mild labor.

Physical examination was essentially negative, although the patient was in poor physical condition, anemic and rundown. Palpation of the abdomen revealed a uterus the size of a full term pregnancy.

Five minims of pituitary extract was given and labor progressed slowly but without untoward symptoms until six hours before delivery, when a large clot was passed. From then on, labor was normal; there was still a moderate amount of bleeding, which did not seem to be alarming until the membranes ruptured spontaneously and bleeding became profuse. The baby was delivered normally, and the placenta was expelled forty five minutes later. Between the birth of the baby and the delivery of the placenta, it was estimated that 300 cc of blood was lost. Fifteen minutes after the birth of the placenta, the patient died.

A partial autopsy revealed no intra abdominal hemorrhage and no rupture of the uterus, but a low implantation of the placenta.

*Comment* This death was evidently caused by hemorrhage during labor and after delivery, and the amount of blood lost during labor was undoubtedly underestimated. Autopsy revealed that hemorrhage occurred from the low placenta, whose site had become separated as the lower segment was taken up and the cervix dilated. It is possible that, had this been realized and the membranes ruptured, possibly with the insertion of a bag, the bleeding would have been entirely controlled. The hemorrhage after the birth of the baby cannot be attributed to the low attachment of the placenta and must have been due to relaxation of the uterus. It is barely possible that the placenta separated with the birth of the child, that its separation was not appreciated as soon as it should have been and that the uterus continued to bleed behind a detached placenta.

Since the uterus was not ruptured, it is not fair to suggest that the use of pituitary extract had anything to do with the fatal outcome, however, when this drug is given in the first stage of labor, it should be given in doses of not more than

1 or 2 minims. Transfusion would have helped this patient, but it is evident that the amount of blood lost during labor and after the birth of the baby was not realized.

## DEATH

CRAIGIN—GEORGE A. CRAIGIN, M.D. of Swampscott, died October 24. He was in his seventy ninth year.

Dr. Craigin received his degree from Harvard Medical School in 1890. He was a fellow of the Massachusetts Medical Society and the American Medical Association.

He is survived by his widow and a sister.

## DEFENSE ACTIVITIES

## CIVILIAN DEFENSE

## OFFICE OF CIVILIAN DEFENSE

Dr. George Biehr, chief medical officer of the Office of Civilian Defense, Washington, D. C., has announced the appointment of a subcommittee of the Advisory Board of the Medical Division to prepare recommendations on protective procedures for hospitals in the event of belligerent action. Dr. R. C. Buerki, dean of the Graduate School of Medicine and director of hospitals of the University of Pennsylvania, Philadelphia, a member of the Medical Advisory Board, is chairman of the new subcommittee, and the members are Dr. W. C. Rappleye, commissioner of hospitals, New York City, Dr. A. J. Hockett, superintendent of Tufts Infirmary, New Orleans, Dr. A. J. J. Rourke, medical superintendent of Stanford University Hospitals, San Francisco, Dr. Joseph Turner, director of Mount Sinai Hospital, New York City, and Dr. Huntington Williams, commissioner of health of Baltimore.

The subcommittee held its first meeting at the Hotel Commodore, New York City, on November 8. With Dr. J. M. Mackintosh, former chief medical officer of the Scottish Ministry of Health, as a guest to advise the group measures for preventing or minimizing damage to buildings, handling of casualties, evacuation, provision and protection of supplies, and training of personnel for specific duties in case of bombing were discussed in detail. The basis for discussion was a study made by a committee of the American Hospital Association of physical defense of hospitals, of which Dr. Hockett is chairman. It is expected that a report will be issued jointly by this committee and the subcommittee representing the Office of Civilian Defense.

Dr. Mackintosh also conferred with the staffs of the medical and civilian protection divisions of the Office of Civilian Defense at the Washington headquarters on November 7, he described in detail Britain's organization of its protective services, its early mistakes and the measures taken to correct them. The basic organization for rescue work in a given area consists of three essential groups with a central control, police, rescue and fire services, ARP control and medical service. One of the early mistakes was the belief that it was imperative to have first aid workers on the scene of a bombing immediately. Better experience showed that injured persons were usually buried under the rubble and glass of their homes and that hours of work by the demolition and rescue squads were often necessary before first aid could be given. Dr. Mackintosh emphasized the necessity for a central ambulance control. Ambulances are dispatched only by the central control and are not allowed to move from a bombed

\* A series of selected cases of the members of the section will be published weekly. Comments and questions by subscribers are welcomed and will be discussed by members of the section. Letters will be addressed to Dr. Raymond S. T. T. Secretary, 330 Dartmouth Street, Boston.

area until routes to hospitals have been surveyed. To stop "panic calls" from individuals, private telephones are cut off the moment an air-raid warning sounds. First-aid posts, in addition to their obvious function of caring for the injured, are invaluable as rendezvous for rescue workers, physicians and nurses, as well as the general population, who may become lost in the blackout, frightened, choked and blinded by dust, he said. In the first-aid posts, the workers can clean up, have a cup of tea and return refreshed to their activities.

## CORRESPONDENCE

### MEDICAL OFFICERS WANTED FOR MOUNTAIN REGIMENT

*To the Editor:* On October 30, 1941, the Secretary of War formally announced to the public the formation of the 1st Battalion, 87th Infantry Mountain Regiment (Reinforced), at Fort Lewis, Washington. This is the first unit ever set up in the United States Army for the specific purpose of conducting winter and mountain-warfare training. The War Department has asked the assistance of the National Ski Patrol in securing names of men who wish to volunteer for this unit, and applications from physicians with interest and ability in skiing are particularly wanted. As in all branches of the services, only men physically and professionally qualified will be accepted. Details may be secured by writing to Mr. Charles M. Dole, Chairman, National Ski Patrol, 222 Graybar Building, New York City.

CHARLES C. LUND, M.D.  
Member of Medical Advisory Committee,  
National Ski Patrol

Boston

### DERMATITIS DUE TO RAGWEED

A twenty-five-old farmer was seen at my office on September 22, 1941. Two years previously, he had had an eruption on his face and arms. This was diagnosed as being due to poison ivy. Recently, while haying, he had noticed that each day his legs became very itchy. His job consisted for the most part of standing in the hay and tossing it down into the barn. A week prior to examination, an itchy eruption broke out on his legs.

Examination showed a marked eruption consisting of erythema, papules and vesicles on the back of the neck, the hands and most of the cutaneous surface of the legs. The eruption was most marked at the popliteal spaces and about the ankles. The patient was put on soothing treatment and stopped work, and was promptly relieved. On October 20, he returned to work, avoiding the hay, but doing some odd jobs about the farm. He suffered a prompt recurrence of the dermatitis. He was patch-tested with various contacts, including weeds from the farm, and showed a marked reaction, consisting of erythema, edema and vesicles, to a plant that was identified by the Bureau of Plant Industry as being common ragweed, *Ambrosia artemisiifolia*.

Although most physicians are cognizant of the reactions resulting from contact with poison ivy, oak or sumac, they are apt to forget that other plants may cause a dermatitis.

JOHN G. DOWNING, M.D.

520 Commonwealth Avenue  
Boston

## BOOK REVIEWS

*The Minds and Nerves of Soldiers.* By Edward L. Hanes, M.D. 8°, cloth, 221 pp. Pasadena, California: Login Press, 1941. \$3.00.

Dr. Hanes, who served as a member of the Neuropsychiatric Service of the United States Army during World War I, has reviewed his experiences and published his opinions about patients and treatment; the volume is based on an extraordinary number of private documents that he has preserved. Many of the examples given are detailed interviews between the examiner and the recruit. Others are details of the case histories of men, either injured or suffering from psychoneurotic manifestations accompanying warfare. Because this manuscript was apparently written largely at the time the observations were made, there is a freshness about the material not found in the ordinary compilation. The case histories and long notes of interviews, however, are not peculiarly integrated. Because of the author's wide experience, the book has considerable value as a record of neuropsychiatric disease occurring in American soldiers, both in this country and abroad, during World War I. There is no index.

*The Avitaminoses: The chemical, clinical and pathological aspects of the vitamin deficiency diseases.* By Walter H. Eddy, Ph.D., and Gilbert Dalldorf, M.D. Second edition. 8°, cloth, 519 pp., with 28 illustrations and 40 plates. Baltimore: Williams and Wilkins Company, 1941. \$4.50.

As in the first edition of this excellent book, the aim of the authors is to present a small manual on the nature of the various vitamins and their functions considered from the clinical, chemical and pathological points of view. This new edition necessitated the rewriting of most of the text. A feature of work that will undoubtedly attract and profit all readers is the co-ordination and readability of the chapters. The authors make a special effort to identify underlying principles and mechanisms. A considerable number of new illustrations have been added, and the references carefully checked. It is well to quote the opinion of Dr. James Ewing, the eminent pathologist, who writes in the "Foreword," "The preparation of the first comprehensive treatise in English on the pathological responses to vitamin deficiencies emphasizes the importance of the application of morphological control in the study of vitamins."

*A Textbook of Clinical Pathology.* Edited by Roy R. Kracke, M.D., and Francis P. Parker, M.D. Second edition. 8°, cloth, 780 pp., with 223 illustrations, 26 tables and 34 colored plates. Baltimore: Williams and Wilkins Company, 1940. \$6.00.

This is an unusually fine textbook of clinical pathology, the work of experienced teachers in the field, all of whom are teachers in the Middle Western and Southern medical schools. They have succeeded in making it a complete treatise that covers comprehensively, accurately and lucidly every aspect wherein the laboratory may aid in clinical diagnosis. The text is profusely illustrated.

The work is fully up-to-date. Among the many new features are a chapter on the determination of vitamins and hormones and, in the section on clinical chemistry, a description of the methods for determining the sulfonamides in the blood and urine.

## HIATUS ESOPHAGEAL HERNIA\*

With Special Reference to a Comparison of Its Symptoms  
with Those of Angina Pectoris

CHESTER M. JONES, M.D.†

BOSTON

NEARLY one hundred and seventy years ago, Heberden<sup>1</sup> gave his classic description of angina pectoris. He noted:

The pain is sometimes started in the upper part, sometimes in the middle, sometimes at the bottom of the os sterni, and more often inclined to the left than to the right side. It likewise very frequently extends from the breast to the middle of the left arm. The pain sometimes reaches to the right arm as well as to the left and even down to the hands.

Heberden also mentioned such variations as pain in only one arm and radiation to the jaws or to the epigastrium.

In commenting on the explanation of anginal pain, White<sup>2</sup> states:

Many different conditions can cause pain in the chest even referred to the arms, easily confused with angina pectoris dependent on coronary disease. The gastric and esophageal etiology is but one of many, although more difficult to distinguish than others. The more frequent radiation of the pain of angina pectoris to the left arm than to the right would not seem to be consistent with the possibility of radiation of pain from the esophagus itself, which should be distributed equally to both sides.

Because of the serious prognostic implications inherent in a diagnosis of angina pectoris or coronary heart disease, it is essential to emphasize the diagnostic errors that are frequently made. One source of confusion in the interpretation of symptoms of suspected cardiac disease is the so called "hiatus" or diaphragmatic hernia.

This anatomic abnormality apparently was first described by Paré in 1575. The first suggestion concerning associated symptoms was given by Morgagni<sup>3</sup> in 1769. He recounted in some detail the history of a person suffering from a "vehement

cardialgia" who was subsequently shown to have a traumatic diaphragmatic hernia. The earlier clinical descriptions of this condition were of necessity concerned with the diagnosis and symptomatology of lesions of a magnitude that could easily be noted on physical examination or by routine x-ray studies.<sup>4-7</sup> In most cases, the hernias were traumatic in origin and represented problems that were distinctly surgical. Even in 1938, Harrington,<sup>8</sup> in an excellent discussion of esophageal hiatus hernia, noted that almost two thirds of his patients had large hernias that filled the posterior mediastinal space and encroached on the left or both thoracic cavities. In the earlier clinical discussions of diaphragmatic hernia, the symptoms described were either epigastric distress or pain associated with vomiting, or intrathoracic fullness and tightness, with palpitation and dyspnea. Undoubtedly, these thoracic symptoms were due essentially to displacement of the mediastinal contents by abdominal viscera contained in the large hernial sac. Portis,<sup>9</sup> in 1925, believed that the signs and symptoms of diaphragmatic hernia were quite definite in large hernias and obscure or absent in small ones. A few years earlier, Soresi<sup>10</sup> stated that it was impossible to define the symptomatology peculiar to small hernias, although he believed that they were likely to give serious trouble. He observed that large hernias were easily diagnosed when their existence was suspected, but that small ones were frequently not diagnosed correctly and therefore were improperly treated—and even when suspected, were not always demonstrable by x-ray examination. In 1930, Moore and Kirklin<sup>11</sup> expressed the opinion that "the clinical significance of small, impermanent hernia at the hiatus, which are demonstrable only under more or less artificial conditions, has not yet been determined." Ten years later, Guthrie and Jones<sup>12</sup> noted that hernias in-

\*From the Medical Clinic, Massachusetts General Hospital and the Department of Medicine, Harvard Medical School.

†Clinical professor of medicine, Harvard Medical School, physician, Massachusetts General Hospital.

volving only a small portion of the cardiac end of the stomach may produce more symptoms than the large ones. In the latest article on the subject, Polley<sup>12</sup> states, that no relation between the severity of symptoms and the type or size of hiatus hernia could be demonstrated.

In the earlier reports of cases of diaphragmatic hernia, histories simulating angina pectoris or heart disease were infrequent. Hedblom,<sup>4</sup> in 1925, discussing symptomatology in 378 patients, mentioned only 86 with thoracic symptoms; of these, only 19 had pain in the thorax and palpitation, and only 2 had pain in the left shoulder. Nine years later, in a review of more than two hundred articles, he<sup>13</sup> mentions dyspnea, cough, palpitation, cyanosis and intrathoracic fullness under thoracic symptomatology. He does not refer specifically to pain simulating that of angina pectoris. Healy,<sup>14</sup> in 1925, noted that substernal pain associated with regurgitation of gastric contents was common, and this symptom in association with diaphragmatic hernia has been observed in individual cases by various authors. Pain radiating into the left shoulder, upper arm and even to the hand has been similarly mentioned in single case reports.<sup>7, 12, 15-28</sup> Nevertheless, Harrington,<sup>29</sup> in a recent review, regards diaphragmatic hernia as an unlikely source of error in the diagnosis of heart disease. Polley<sup>12</sup> likewise mentions anginal pain as the least common of all the symptoms of hiatus hernia. That the manifestations of myocardial infarction may be simulated by a diaphragmatic hernia has been noted by very few. In a discussion of coronary thrombosis, Herrick<sup>30</sup> stated that he knew of only one such case. Reid<sup>28</sup> clearly describes nocturnal attacks of a severity comparable to the pain encountered in myocardial infarction.

Truesdale<sup>31</sup> stated that, in differentiating these attacks and those of angina, one may be aided by noting with the former the atypical radiation of pain to the back and its occurrence without effort and the slight evidence of heart disease. Moschowitz<sup>32</sup> admitted that 3 of his 21 patients had some symptoms resembling those of coronary disease, but stated that none had typical radiation of pain and that in none were the symptoms initiated by exertion or emotional disturbances.

Von Bergmann,<sup>33</sup> in 1932, was one of the first to exhibit interest in the relation between the pain of diaphragmatic hernia and that of angina pectoris. None of his 17 patients, however, had shoulder or arm pain, and substernal pain was noted in only 5. Interest in the possible mechanism of the pain in hiatus hernia and its effect on the heart

led him to study the so-called "gastrocardiac complex."

These divergent opinions in the literature relative to the symptomatology of hiatus esophageal hernia have led me to review in detail my experience with the disorder in private and hospital practice. The frequency with which the clinical histories of these cases suggested organic heart disease was impressive. I believe that this study throws some light on the diagnostic problem of esophageal hiatus hernia, as well as on the mechanisms involved in the production of symptoms.

#### CLINICAL MATERIAL

The material includes a series of 91 cases of small hiatus hernia and 37 cases of large hernia. Fifty of the hernias were encountered in private patients, and 78 in patients on the wards or in the Out Patient Department of the Massachusetts General Hospital. The group represents selected material only in the sense that fairly definite information was required concerning the size of the hernia, and the study included only those patients whose presenting symptoms were referable to the hernia. Patients in whom no accurate roentgenologic descriptions or exact measurements of the diaphragmatic hernias were recorded were excluded. Obviously, these criteria did not apply to a large number of patients in whom hiatus hernias were demonstrated accidentally. This seems appropriate because diaphragmatic hernias, regardless of size, may be completely asymptomatic.

The size of the hernias classified as "small" did not exceed a maximum diameter of 7 cm. Most of the cases thus classified presented x-ray evidence of a hernial sac whose greatest diameter did not exceed 4 cm. In the private cases, the average maximum diameter of the hiatus hernias was 3.8 cm., whereas measurement of the small ones taken from hospital records revealed an average maximum diameter of 4.5 cm. The reason for this difference in size is not entirely clear, but it is highly probable that the private patients came for examination sooner after the onset of symptoms than those who were studied in the hospital. All clinical evidence seems to indicate that diaphragmatic hernias tend to become slowly but progressively larger as symptoms continue. It is of interest that 9 of the private patients were examined twice before an accurate demonstration of the hernia was made, and three x-ray examinations were needed to establish the diagnosis in several patients, even though in each case it was strongly suspected. The hernias that were designated as "large," had diameters exceeding 7 cm. and con-

tained, in most cases, what was estimated to be one third or more of the stomach. No difference was noted between the complaints of patients with a so called "short esophagus" and those with para-esophageal or hiatus hernias; thus, no such differentiation has been made in this study.

As was to be anticipated from all previous reports, most of the patients under consideration were in the later decades of life and were overweight. The average age was fifty-five. A diagnosis of heart disease was considered in 24 of the 50 private patients but was finally accepted as tenable in only 13 cases after adequate evaluation of physical signs and electrocardiographic findings. Nine of the hospital cases exhibited definite cardiac abnormalities, all of which were associated with hypertension or coronary sclerosis. Because of symptoms that were at times confusing, it is noteworthy that gallstones or evidence of gall-bladder disease was present in 12 private patients and in 10 hospital patients. This incidence of heart disease and biliary-tract disease is entirely consistent with the age distribution of the patients under consideration, and corresponds with clinical experience presented in other communications on diaphragmatic hernia.

#### CLINICAL OBSERVATIONS

Of especial interest in the present discussion is an analysis of the symptoms experienced by these patients. The symptoms are considered in relation to a possible diagnosis of heart disease and particularly in relation to the diagnosis of angina pectoris. In evaluating the symptomatology associated with small hernias, special attention is directed to patients encountered in private practice, since a perusal of the records indicates that a more accurate and more detailed history was taken in this group than in the hospital group. The private patients are of special interest inasmuch as they exhibited a relatively high level of intelligence and descriptive ability.

Table 1 shows the incidence of various symptoms experienced by patients with large and small diaphragmatic hernias. Substernal pain was experienced by over one third of the 91 patients with small hernias but occurred in only 5 of the 37 with large hernias. It was more than twice as common in the private patients with small hernias as in ward patients. Shoulder pain, usually on the left, was noted in about one quarter of the patients with both types of hernia, although it appears to have been more frequent in the hospital patients with small hernias than in any of the others. The exact location of this pain was

not accurately described in the majority of records. In some cases, it was distinctly a trapezius-ridge pain, usually on the left, but in others, it was localized at the tip of the acromion process. Radiation of pain into the arm occurred in 8 of 91 patients with small hernias, 6 of whom were

Vomiting (or regurgitation)	36	15	21	3
Heartburn	1	14	1	0
Dysphagia	0	3	1	0

from the private group. Hand or finger pain was described by 5 of the latter. Four patients with large hernias noted radiation of pain into the arm, but in no case did it extend to the forearm, hand or fingers. Although the subjects usually described the sensation as pain, at times only tingling or numbness occurred. Palpitation was noted by only 6 patients with small hernias, and by 4 patients with large hernias. Dyspnea was somewhat more frequent. It was noted in one tenth of the small-hernia group and in about one third of the patients with large hernias. Curiously enough, cough and hiccough were not noted in any of the records, although these symptoms undoubtedly occur in patients with large hernias.

Epigastric pain occurred in two thirds of the hospital patients with small or large hernias, but was mentioned by only 19 of the 45 patients in the private group with similar lesions. Costal margin pain was noted on either the right or left side or both by 21 of the 91 patients with small hernias and by 11 of the 37 with large defects. About one fourth of the patients complained of pain in the back, usually in the interscapular area, and 4 of the private patients with small hernias noted pain directly under the left or right scapula. Two of the latter had gall bladder disease. Only one of all the patients complaining of pain in the back designated this as the sole symptom. In every other case, back pain was present in combination with epigastric or substernal pain. Axillary pain was noted in 3 patients with small hernias. Difficulty in swallowing was noted in only 4 cases, 3 of which occurred in patients with small hernias. Heartburn appeared to be rather characteristic of

small hernias in private patients. Fourteen of the 45 private patients complained of this symptom, whereas it was noted in the records of only 2 of the ward patients. This difference may be more apparent than real, since it was a minor symptom in many cases, and since more careful questioning might have disclosed its presence in other patients of the hospital group. Its possible importance will be discussed later.

It is noteworthy that right-sided pain involving the chest, shoulder or arm was observed by 13 of the patients with small hernias and by 6 of those with large hernias. Four of the former complained of tightness or constriction in the throat, and 2 of facial pain during severe attacks.

Bock et al.<sup>34</sup> noted the frequency of bleeding in diaphragmatic hernia. In the cases under discussion, bleeding occurred in 22 patients with small hernias and in 6 with large lesions. The evidence

this symptom. It occurred most frequently in association with epigastric or costal-margin pain in patients with large hernias. It was not uncommon, but was less frequently noted, in patients who had substernal pain or distress without epigastric discomfort. Regurgitation, rather than frank vomiting, was the rule in the group of private patients with the small lesions.

It is of especial interest in a comparison of the symptoms of diaphragmatic hernia and those of heart disease to consider initiating factors and measures that afford relief. For such a comparison, the records of the 50 private cases are in sufficient detail to warrant presentation. The findings are presented in Table 2.

Eight of 25 patients with substernal pain stated that exertion frequently initiated the symptom. When there was radiation to the shoulder, 4 out of 7 stated that exertion was a precipitating factor;

TABLE 2. Factors Affecting Symptoms Associated with Small Hernias in Forty-Five Private Patients.

SYMPTOM	CAUSE				EFFECTIVE MEANS OF RELIEF		
	EXERTION	EMOTIONAL FACTORS	EXCESSIVE FOOD	LYING DOWN	NITRO-GLYCERIN	ATROPINE	BELCHING
Substernal pain (25 patients)	8	12	15	9	8	17	8
Shoulder pain (7 patients)	4	6	4	4	3	5	0
Arm hand pain (6 patients)	3	6	3	4	3	3	3
Epigastric pain (19 patients)	4	5	13	9	3	10	5
Heartburn (14 patients)	5	4	7	3	4	7	5

of hemorrhage varied from the presence of occult blood in the stools to frank, massive hematemesis.

A consideration of the developmental pattern of these symptoms is of interest. Of the 45 private patients with small hernias, 25 had substernal pain, but only 8 had associated epigastric pain. Of the 46 hospital patients with slightly larger hernias, 9 had substernal pain, and 5 of these had concomitant epigastric distress. Only 5 of the 37 patients with large hernias had substernal distress, but 4 of these had associated epigastric symptoms. In other words, about one third of the private patients with small herniations of the stomach through the paraesophageal orifice had symptoms that were both thoracic and upper abdominal. The majority of those complaining of substernal distress, with or without radiation to the shoulder or arm, were free from abdominal symptoms. It appears, however, that patients with large hernias and thoracic symptoms had a higher incidence of associated epigastric discomfort than those with small lesions.

The frequency with which vomiting is associated with diaphragmatic hernia has been noted by all observers. In the cases under discussion, 75 of the entire group of 128 patients complained of

and in 3 of the 6 patients whose pain radiated from the substernal area through the shoulder and down the arm it was a frequent cause. It should be emphasized that *in no case did exertion invariably produce pain*, although it was frequently the important or sole cause in individual attacks. Furthermore, a careful analysis of the histories obtained from the group of private patients indicates that, without question, nervous tension and, particularly, acute emotional disturbances initiated symptoms suggesting angina pectoris. Of 25 patients who experienced substernal pain, 12 stated that emotional upsets frequently caused the symptom to appear, and when there was radiation of pain from the substernal region to the shoulder and arm, it was found that nervous tension almost invariably acted as an exciting cause. Such observations are, of course, in sharp conflict with the suggestion by Moschowitz<sup>32</sup> that typical anginal pain, especially that following exertion or emotional disturbances, is never associated with diaphragmatic hernia. By way of contrast, it is of some interest that, of 19 patients with attacks of epigastric pain, only 4 noted exertion as an inciting factor; similarly, only 5 believed that emotional disturbances played a causative role.

The intake of food, particularly of a large meal, was responsible for initiating substernal pain in 15 patients out of 25 and was an adequate stimulus for shoulder, arm and even finger pain in half the patients complaining of this type of pain radiation. Of 19 patients with epigastric distress or pain, 13 said that the symptom was frequently precipitated by eating. Somewhat less frequently, the act of lying down initiated symptoms, regardless of whether they were noted in the thorax, with radiation to the shoulder and arm, or whether they were located in the epigastrium.

Of significance also in this group of private patients is the effectiveness of certain measures used to obtain relief. Of 25 patients complaining of substernal pain, 10 received nitroglycerin in ordinary therapeutic doses, and 8 frequently obtained relief from the drug. Pain radiating to the left shoulder and arm was relieved in 3 patients out of 4 who tried it. Only 3 of 19 patients who complained of epigastric discomfort were given the drug, but all obtained some relief. It should be added that *in no case was the relief of symptoms following the use of nitroglycerin as regular as that noted in typical anginal attacks*, although at times complete relief was obtained regardless of the precipitating cause. Atropine or belladonna gave distinct relief to 17 out of 18 patients who used it for substernal distress, and all of 5 patients with shoulder pain at times obtained real benefit from its use. Similarly, 10 out of 11 patients with epigastric pain were greatly helped by atropine or one of its derivatives. Belching gave a certain temporary relief in a few patients with substernal and epigastric pain, but it did not relieve those whose pain radiated into the shoulder and arm. Various antacids were used with occasional success, but relief was not noted often enough to warrant further comment. It is my impression, however, from recent experiences with various preparations that they may afford valuable therapeutic aid.

Finally, it is germane to the discussion to comment on the infrequency with which heart disease was encountered in this study. Among the 25 private patients with small hernias who complained of substernal distress or pain, there were 6 cases of organic heart disease. Of these 25 patients, 8 had pain on exertion, but only 4 had cardiac disease. *Only one patient of the 7 who had pain radiating into the shoulder or arm had demonstrable heart disease, although 3 often noted pain after exertion.* Heart disease was not present in a single patient with epigastric pain after exertion. Among 15 patients who complained of substernal or epigastric pain following excitement,

there were only 3 who had heart disease. Of the hospital patients with large hernias, 8 experienced shoulder pain, and 1 had pain in the left arm but not in the shoulder; none of these patients had heart disease. Altogether, 15 patients with small hernias and 16 with large hernias experienced dyspnea and palpitation, yet only 4 had heart disease.

Thus, a careful analysis of the records of the 128 cases indicates that only 11 patients had heart disease that may have contributed to the presenting symptoms. Of these, 9 had the symptom of substernal pain with or without radiation. All the latter had small hernias, and the symptom was relieved in at least 3 by the use of atropine, a drug not efficacious in relieving the pain of angina pectoris. Thirty patients had substernal pain without demonstrable heart disease, and 16 others who were free of heart disease complained of shoulder or arm pain without a substernal component.

The foregoing observations direct attention to certain points. Symptoms characteristic of heart disease, such as substernal distress occasionally radiating to the left shoulder and down the arm into the little and ring fingers, were encountered frequently in patients with hiatus hernias. Exertion, nervous tension and large meals were common precipitating factors. Relief was frequently obtained by the use of nitroglycerin. Substernal distress occurred most frequently in the patients with the smallest hernias.

Certain points of difference may aid in distinguishing hernial from cardiac symptoms. Right-shoulder pain is relatively uncommon in angina pectoris. Only 1 patient with hernia and demonstrable heart disease had right-shoulder pain; this symptom, however, was noted in 19 patients with hernias in the absence of heart disease. Although exertion frequently precipitated substernal pain in the patients with hernias, it rarely did so consistently. There were notable cases in which violent exertion on one occasion would induce pain and on another would fail to do so, although dietary indiscretions and nervous tension usually precipitated attacks of pain or discomfort. A large meal or the injudicious use of alcohol frequently caused symptoms, particularly in the presence of emotional disturbances. Nocturnal attacks when the patient was in a recumbent position were not uncommon. A close relation between the onset of symptoms and the act of lying down or bending forward was noted in two fifths of the private patients and has been stressed by most observers. A further difference between the patients with hernias and those suffering from angina pectoris lies in the frequent and striking relief the former

obtained by the consistent use of atropine. Although nitroglycerin afforded dramatic relief from pain in some cases, it frequently failed.

It is apparent, then, that esophageal hiatus hernia is an important cause of symptoms, which may be confused readily with those due to serious heart disease. At times, the correct differentiation can be made only after a most careful scrutiny of all available facts, including a meticulous history. This is particularly true in very small hiatus hernias, which can be demonstrated only by extremely careful x-ray examination and then only when they are suspected. Unlike most observers, I am convinced that small hiatus hernias have a reasonably characteristic set of symptoms, which under careful observation can be properly diagnosed.

#### MECHANISM

Various theories have been advanced regarding the cause of so-called "anginal" pain. That it can occur as the result of coronary-artery disease can scarcely be doubted. When of coronary origin, it is typically initiated by exertion or sudden emotion. It is usually considered to be true referred pain<sup>35</sup> mediated over sensory afferent neurones, with which the aorta and heart are so richly supplied.

A variety of explanations have been offered for the pain associated with diaphragmatic hernia. Numerous authors have attributed dyspnea, palpitation and cyanosis, as well as the sensation of tightness in the chest, to actual displacement of the heart and mediastinal organs by the contents of the hernial sac. Such an explanation is reasonable when the hernia is large and contains a major portion of the stomach or other abdominal viscera. That the size of the hernia is active in the production of these symptoms is evident from the present study. Dyspnea was present in one third of the patients with large hernias and in about one tenth of the 91 patients with small hernias.

Aside from the effects of displacement of the mediastinum, any attempt to explain the symptoms of paraesophageal hiatus hernia must be based on a consideration of the sensory pathways included in the trunks of the vagus and phrenic nerves and in the afferent sensory neurones of the upper thoracic trunks. Von Bergmann,<sup>33</sup> in 1932, after a careful investigation of what he termed the "gastrocardiac complex," was convinced that the cardiac symptoms associated with diaphragmatic hernia were due to pressure on the vagus fibers, with consequent reflex disturbances of the coronary circulation. Jackson and Jackson<sup>36</sup> at-

tempted to prove that the pain of angina pectoris was not directly related to the heart. They believed that air or other stomach contents became trapped in the stomach or the esophagus, with resulting anginal pain. They attributed this to acute spasmodic, unco-ordinated contractions of the esophagus and stomach. This explanation seems rather far-fetched, although there can be little doubt that clinical and experimental observations have demonstrated a close relation between esophageal, gastric and cardiac functions. Morrison and Swalm,<sup>37</sup> for example, reported definite cardiac disturbances as indicated by electrocardiographic changes following balloon distention of the esophagus in patients with organic heart disease. These observations were made on patients suffering from typical anginal pain associated with heart disease, and merely prove that pain caused by intracardiac disease may be initiated by distention of the esophagus. These authors were able to show that the spasmodic, unco-ordinated movements of the esophagus and stomach described by Jackson and Jackson did not occur in attacks of angina pectoris. Kuhlmann,<sup>38</sup> Kaiser<sup>39</sup> and Kalk and Koelsch<sup>40</sup> also believed that esophageal irritation produced pain similar to angina by means of a vago-vagal reflex affecting coronary blood flow, but their findings are not conclusive. The notion that esophageal or gastric disturbances may be responsible for widespread vagal stimulation with resulting bradycardia finds ample confirmation in clinical literature and in bedside observations. That such a phenomenon in the absence of heart disease is responsible for reflex coronary constriction, which results in anginal pain in patients with diaphragmatic hernia, is more difficult to believe. The experiments of Hinrichsen and Ivy<sup>41</sup> seem to offer definite evidence against such a mechanism. Furthermore, it is the consensus among neurologists that the sensory afferent fibers contained in the vagal trunks convey few, if any, important visceral sensations except nausea.<sup>42</sup>

It seems more logical to assume that the discomfort or pain experienced by patients with diaphragmatic hernia is secondary to intraesophageal or intragastric disturbances, with typical visceral or referred pain, or to a local disturbance of the diaphragm. It is of incidental interest to refer to a rarely mentioned article published in 1887 by Dana,<sup>43</sup> who gives an excellent description of what he terms "pseudoanginal" (substernal) pain of gastric origin. His carefully illustrated article on transferred pain precedes slightly the classic article by Ross<sup>44</sup> and the later ones by Head<sup>45</sup> and Mackenzie<sup>46</sup> on referred or visceral pain. Pain stimuli

due to disturbances in the diaphragm, heart, esophagus and stomach are carried over the so-called "visceral afferent neurones" and result in so-called "viscerocutaneous pain" or referred pain. It is generally accepted that cardiac pain is mediated over the first to fifth thoracic segments, with a possible spread to the sixth. The most convincing evidence for this is the apparently established fact that bilateral section of the posterior roots of the first six thoracic nerves completely abolishes the typical pain of angina pectoris.<sup>47</sup> Pain radiating over the upper five or six thoracic segments is

Capps<sup>48</sup> has shown that pain stimuli arising from the tendinous portion of the diaphragm travel over the afferent neurones in the phrenic nerve and are distributed to the skin areas of the third, fourth and fifth cervical segments. Because of developmental variations, the distribution of the second cervical segment may occasionally become involved. It should also be noted that the fifth cervical segment includes a small area on the radial surface of the forearm just above the base of the thumb. Thus, irritation of the tendinous portion of the diaphragm typically gives shoulder

FIGURE 1 *Cervical and Upper Thoracic Dermatomes (Foerster<sup>49</sup>)*

felt over the precordium, axilla, the back from the level of the first thoracic vertebra to the sixth, and along the inner half of the arm and forearm to the base of the little finger (Figure 1). The sensory innervation of the dorsal and palmar surfaces of the little finger is included in the eighth cervical segment. Any adequate explanation of the ulnar pain of coronary origin must therefore necessitate the hypothesis that painful stimuli entering a given segment may spread beyond the original level of stimulation to one or more neighboring segments. Thus, somewhat excessive stimulation in the first thoracic segment might result in an additional area of eighth cervical reference, inducing the little finger pain so frequently noted in anginal attacks.

pain and occasionally pain in the throat, facial and nuchal regions, or pain down the arm to the base of the thumb, but never along the so called "ulnar distribution" to the little finger.

Irritation of the marginal portion of the diaphragm produces painful sensations over the segmental distributions of the seventh to the twelfth dorsal (intercostal) nerves,<sup>48</sup> an area extending from below the nipple line to the hypogastrium anteriorly, and from the midscapular region to the iliac crests or below posteriorly. Inasmuch as the attachments of the crura of the diaphragm are at the level of the first or sometimes the second lumbar vertebra, it is probable that unusual irritation of the marginal portion of the diaphragm, with traction on the crura, could be associated with

pain in the first lumbar segments, involving the hypogastrium and the area over the lateroposterior aspect of the hip. It is essential to point out that reference of pain over the middle and lower thoracic segments from the marginal portion of the diaphragm tends to be zonal in distribution and not essentially midline—that is, substernal and midepigastric.

Exact information concerning the anatomic distribution of viscerosensory fibers to the esophagus is not available. According to several careful investigators,<sup>42, 49</sup> the esophagus derives its sensory innervation from the fourth and fifth or the fifth and sixth thoracic segments. If this is true, it follows that painful sensations arising from the esophagus will be referred over the segments corresponding to the fourth and fifth (and sixth) thoracic nerves. However, it is more reasonable to believe, on the basis of embryonic development, that the afferent sensory neurones supplying the esophagus lie in the area between the first and sixth thoracic segments. In Head's<sup>45</sup> early work, he observed pain at the episternal notch in association with upper esophageal disease, and ample confirmation of this lies in the demonstration that distention of the esophagus at various levels produces midline substernal pain or discomfort at levels from the episternal notch to the xiphoid. The upper border for segmental pain referred from the esophagus would therefore be at a level well within the first dorsal segment, and any overflow from somewhat excessive stimulation might well spread over that section included in the eighth cervical segment, involving the forearm and little finger. Lateral segmental spread of painful sensations from the esophagus occurs when the stimulus is great, but ordinarily is felt only in or near the midline, in distinction to the spread of painful sensations following irritation of the margin of the diaphragm. Two other points are of significance in this connection. I<sup>50</sup> and Payne and Poulton<sup>51</sup> have demonstrated clearly that heartburn is an esophageal symptom, arising particularly from stimulation of the lower portion of the organ. Furthermore, during sudden distention with an inert suspension (barium) of the lower end of the esophagus, with resultant heartburn, it was constantly noted that spasm occurred in the cardiac end of the esophagus. At the same time, active peristalsis was seen to carry the barium suspension upward, at times as high as the upper end of the esophagus. This evidence of abnormal neuromuscular activity was invariably accompanied by a burning or painful sensation that traveled upward toward the episternal notch. Somewhat similar findings were made by Kuhlmann,<sup>38</sup> who,

as already noted, observed the appearance of substernal pain radiating into the left arm in 5 patients with small diaphragmatic hernias. This pain was found to occur when the hernial sac, which was the size of a walnut, was distended with a thick barium suspension. No cardiac abnormalities were noted while the patients were experiencing this angina-like pain, but the significant observation was made that the entire esophagus showed evidence of a marked increase in tone, increased peristaltic activity and local areas of spasm.

A useful point in localizing the source of the painful sensations in patients with diaphragmatic hernia is the frequent occurrence of marked congestion, superficial irritation and even superficial erosion of the lower end of the esophagus or of the portion of the stomach included in the hernial sac. Clerf and Manges<sup>52</sup> and others have observed such changes by esophagoscopy. They were also observed in several of my patients.

Disturbances of the fundic portion of the stomach have been shown by numerous observers to result in painful sensations referred anteriorly to the midline, subxiphoid or high epigastric region,<sup>53</sup> an area corresponding to the seventh to ninth thoracic segments.

On the basis of these considerations, it seems highly probable that the pain of hiatus or diaphragmatic hernia is mediated over visceral afferent fibers supplying the esophagus and the cardiac or fundic portion of the stomach, or over the sensory afferent fibers from the diaphragm contained in the phrenic or middle or lower thoracic nerves. Overflow to adjacent low cervical or low thoracic segments undoubtedly occurs. Overdistention of the lower end of the esophagus or the herniated portion of the stomach, with or without an associated localized esophagitis or gastritis, may thus be responsible for the production of anginal pain in any or all of its components. The shoulder pain is largely due to diaphragmatic irritation, probably by tension and traction exerted on the hernial orifice by the distended viscus contained therein. The relief obtained following the use of nitroglycerin or atropine indicates that esophageal and upper gastric disturbances are the most important components in the painful sensations experienced in this condition. This statement seems particularly applicable to the mechanism of pain noted by patients with small hernias. The role played by the vagus nerve is undoubtedly purely motor and is concerned in the production of neuromuscular disturbances, such as the spasm and abnormal peristalsis noted in the esophagus. Smooth-muscle disturbances may be initiated by a local in-

inflammatory process at or near the cardiac sphincter, by distention of the herniated portion of the stomach or by central stimulation of the esophagus secondary to marked emotional tension or excitement. In all probability, acute emotional upsets actually affect the cardiac sphincter itself, with resultant achalasia due to sympathetic (adrenergic) overstimulation. These motor disturbances are similar to those occurring in any hollow viscus and form the basis for most, if not all, visceral pain.

### TREATMENT

Treatment of the symptoms of hiatus hernia, especially those caused by small lesions, is essentially medical. Phrenicectomy or surgical repair is justified only in large hernias or when medical measures fail to give relief. A light, bland diet, taken frequently, with especial care that individual meals are relatively small in amount, is indicated. Antacids, such as aluminum hydroxide gel, are efficacious, and atropine, belladonna, Trasentan or other spasmolytics may afford additional relief during periods marked by the appearance of symptoms. Acute symptoms are frequently helped by nitroglycerin, which at times may be used advantageously before the intake of food or before retiring. The assumption of an upright or semi-upright position after eating is to be desired. Adequate rest, physical and emotional, sedation when needed and the avoidance of exercise shortly after the intake of food are also valuable measures. A further important therapeutic consideration is the proper evaluation of coronary heart disease and cholelithiasis when either condition accompanies the hernia.

### SUMMARY

A series of observations made on 128 patients with diaphragmatic hernias is presented. Especial consideration is directed to the symptomatology of this condition.

The frequency with which anginal pain due to coronary-artery disease may be duplicated by hiatus hernia is discussed.

Particular attention has been paid to the character of the symptoms observed in patients with small hernias. These symptoms are considered to be fairly typical, relatively frequent and of real clinical significance.

A discussion of the probable mechanisms involved in the production of the pain of hiatus hernia is given, and an attempt is made to clarify the routes over which hernial pain is mediated. The reasons for the similarity between hernial and cardiac pain are thus demonstrated. The points

of differentiation between pain due to hiatus hernia and that secondary to heart disease are outlined.

A summary of the medical procedures that are effective in the treatment of the symptoms of hiatus hernia is presented.

## THE DOCTOR OF ONE HUNDRED AND FIFTY YEARS AGO\*

HENRY H. AMSDEN, M.D.

CONCORD, NEW HAMPSHIRE

THE past century and a half has witnessed greater progress in scientific discovery and invention than any other period in the history of civilization, and the science and art of medicine have kept fully abreast of progress in other fields of human endeavor and research. Medical science has utilized these discoveries for the prolongation of life and the relief of human suffering, whereas mankind as a whole has employed them in warfare for the destruction of life. I have only to cite the uses of electricity, steam, the gasoline explosive engine and discoveries in chemistry to prove these facts.

To visualize medical practice in New Hampshire in 1791, one hundred and fifty years ago, one must first form a picture of life and living conditions at that time. There were then fourteen states in the Union, Vermont having been admitted in 1790. Portsmouth was the largest city in New Hampshire. What is now Manchester was a part of the township of Londonderry. Dartmouth College was only twenty-six years old, and Dartmouth Medical School was not founded until 1798. Land travel was by horse or ox-drawn vehicle, and mostly on horseback outside the towns or along the main thoroughfares. The first New Hampshire turnpike, between Concord and Portsmouth, was opened in 1796, and the Londonderry turnpike in 1806. Light was obtained from whale-oil lamps or tallow or sperm candles. Wood was the principal fuel, and central heating was unknown.

The majority of the original members of the

Society lived in or near Rockingham County. Dr. John Rogers, however, came from Plymouth, a two days' journey from Exeter.

### MEDICAL EDUCATION AND QUALIFICATIONS FOR PRACTICE

One of the principal reasons for founding the New Hampshire Medical Society was to provide some licensing body to pass on qualifications for the practice of medicine, and the Society continued this function until the formation of the Board of Medical Examiners in 1897. Josiah Bartlett, who was the prime mover in the establishment of the Society, indulged the hope that it would do much to suppress the "dangerous host of illiterate quacks." To effect this object, he proposed that a law should be passed to prevent physicians in New Hampshire from recovering judgments in courts of law unless they had been previously examined and licensed by the Society. This, however, did not become a law.

*The American Herald of Liberty*<sup>1</sup> gives the following list of qualifications of candidates for examination before the censors of the New Hampshire Medical Society:

*Section 1.* He [the candidate] shall have a competent knowledge of the English and Latin languages.

*Section 2.* He shall have a general acquaintance with the principles of geometry and natural philosophy.

*Section 3.* He shall have studied three years under the direction, and attended the practice, of some reputable physician, or two years if he shall have received a degree at any college or university, during which time he shall have read the most approved authors in anatomy, physiology, chemistry, materia medica, surgery, and the theory and practice of physic, of all which qualifications a satisfactory certificate from the

\*Presented at the annual banquet of the New Hampshire Medical Society, Manchester, May 14, 1941.

physicians or physician with whom he studied shall be presented to the censors. Previously to his being admitted to examination, the Society earnestly recommends a university education to all designed for the medical profession, and to all students in the various branches taught in the universities.

Then follows a list of thirty-three medical books recommended for reading.

This certainly set a high standard for the physicians of that period.

The first medical school was established in Philadelphia in 1762, but most physicians obtained their education solely from preceptors. Some of the more fortunate, financially, did postgraduate work in London or Edinburgh.

The student accompanied the physician on his rounds, assisted him in operations, and compounded medicines, most of which were put up and dispensed by the doctor. Very often, the student also acted as janitor and hostler.

#### SURGERY IN 1791

Many physicians served during the Revolutionary War and obtained their surgical experience in this manner. Asepsis and anesthesia were, of course, unknown, and the closed cavities of the body—the chest, abdomen, brain and joints—were forbidden ground except in cases of accident or injury. Amputations, reduction of fractures, removal of external growths, lithotomy and cataract extraction were the principal surgical procedures.

Dr Philip Carrigan, a Concord physician, amputated a leg following an accident. Finding his saw too dull, he sent to a neighboring house to borrow a sharper instrument with which to complete his operation. The end of the bone was evidently left bare, for he picked it with a nail and applied New England rum to promote healing. On another occasion, he amputated a finger with a miller and chisel. Many of the major surgical operations at a somewhat later date were performed by "country doctors"—for example, the ligation of the common carotid artery by Dr Amos Twitchell of Keene.

Although the following story has to do with a later period than the one under consideration, it illustrates the belief in the desirability of "laudable pus." Dr E. E. Graves of Penacook sewed up a cut in a man's foot, and the wound healed by first intention. The patient, however, complained that the doctor sewed up all the "corruption" instead of allowing it to escape, and claimed that he never fully recovered from the effects of unskillful surgery. This belief in the necessity for suppuration in wound healing was the reason for the use of the

seton, which was a piece of gauze or bunch of threads or bristles introduced under the skin by a through and through incision, this formed an "issue," and the resulting suppuration was supposed to allow the escape of "peccant humours."

#### MEDICINE IN 1791

The practice of medicine at the close of the eighteenth century had evolved from what might be called the "supernatural period," prior to about 1750, when it was believed that disease was a malign agency to be exorcised by offensive substances.

Medical literature prior to this time is full of most bizarre and ludicrous prescriptions. Levine<sup>2</sup> has covered this subject so thoroughly in a recent paper that it hardly seems necessary to enter into further details in this connection. However, in the light of modern medical science, even the "witches' broth" in *Macbeth*—'eye of newt, and toe of frog, wool of bat, and tongue of dog, and so forth'—may have possessed biologic or vitamin properties.

The materia medica of this period was founded largely on roots and herbs, many of them indigenous to New England. Although the modern physician may question the value of these agents, one must remember that they doubtless made the patient more comfortable in mind and body while Nature was performing the cure, and at least most of them were harmless, which cannot be said for some recent additions to the therapeutic armamentarium. The four Herculean remedies, however,—opium, mercury, Peruvian bark and antimony,—were administered in generous doses. The classic treatment of fevers was a purge one day and an emetic the next, with an occasional and copious bleeding.

Dr Reuben D. Mussey, in his lectures at Dartmouth Medical School, gave specific instructions and indications for bleeding, and according to Josiah Bartlett's daybook, the usual charge for "phlebotomy" was one shilling.

Water, either externally or internally, was thought to be dangerous, and "night air" especially poisonous. The favorite aphorism, "stuff a cold and starve a fever," has persisted, even within the memory of some present-day physicians. A gleam of wisdom appears sometimes, however, for in Brooke's<sup>3</sup> *General Practice of Physic* occurs this sentence: "For it sometimes appears that physicians are called in to prescribe their arcana and think they have cured the disease thereby, which would have ended by the sole benefit of nature."

Diagnosis of disease was limited largely to observation of symptoms, since the ordinary diagnostic instruments—the stethoscope, the clinical thermometer and the means of urinalysis—did not appear until after the turn of the century. Much attention was paid to climate, soil, effects of diet and even astrology. Careful records were made of prevailing winds and variations in temperature in different places, especially in Salisbury, and much importance was attached to these factors in determining the course of disease.

Josiah Bartlett has left a record of success in treating what was called “cynanche maligna” (probably diphtheria), by bark and supporting measures, rather than by the more accepted treatment of bleeding and so forth. It is also a matter of record that he cured himself of a fever by drinking large quantities of cider, in defiance of his medical advisers.

It is no wonder that homeopathy, with its promulgation of an infallible therapeutic law and its substitution of small doses of the “indicated remedy” and the cold compress for the drastic measures then in vogue, was hailed by many as a revolution in medicine.

Inoculation for smallpox was the practice at that time, vaccination being not generally accepted until a later period.

A page from Josiah Bartlett’s daybook gives a picture of an average day’s work: “Benjamin French, bleeding himself. Jonathan Stevens, drawing a tooth. Elisha Winslow, calling and emetic. Elisha Batchelder, cutting child’s tongue.”

Joseph Bartlett, a nephew of Josiah Bartlett, practiced in Salisbury during the latter part of the eighteenth century. Sample extracts from his daybook give the following data:

Ensign Moses Garland to J. Bartlett, *Dr.* May 23, 1778. Bleeding Lydia D. Sleeper, 8 pence. December 4, 1778. Dressing his leg, 7 pence. January 11, 1779. A visit, *Elix. camph. opii theb., G. dracon. mag. alba. cm., Oleum anisi, etc.* and tarrying, 8 shillings.

Whether the 8 shillings was for the medicine or for the tarrying is an open question.

The polypharmacy of this era was confined to drugs; the modern physician prescribes vitamins, biologicals, vaccines and so forth *ad lib.*

Dr. Colby, also of Salisbury, was complained against because he raced horses on the Sabbath; he was so angered that he promptly left town.

Dr. Asa Crosby, later of Gilmanton, began the practice of medicine in Marlborough in 1785. Some time during the year, the authorities warned him to leave town, presumably because they were afraid he would become a public charge. He told them he would be glad to leave if they would pay his bills for professional services rendered.

This was apparently not done, since regrets were expressed by the townspeople because he had to leave.

Dr. Nathaniel Peabody, of Exeter, was imprisoned for debt for twenty years; however, he was allowed the freedom of most of the town and practiced medicine to a certain extent during that time. Dr. Stephen Tenney, also of Exeter, attempted unsuccessfully to reduce a dislocation of the shoulder; his failure so discouraged him that he abandoned the practice of medicine.

Yellow fever, which was such a scourge in other sections of the country, reached New Hampshire in only one epidemic, brought to Portsmouth in 1798 by a sailing vessel.

Influenza was epidemic at times and showed its characteristic clinical picture, with complications affecting the ears, sinuses and lungs.

“Spotted fever” was probably meningitis or typhoid fever, possibly typhus, although apparently sometimes confused with virulent influenza. “Scarlatina anginosa” was malignant scarlet fever. One is struck by the severity of its symptoms as described in medical books of the time; it is, of course, a fact that scarlet fever is much less virulent now than it was even a generation ago.

The physicians of this period were as a class more active in civic and political fields than those of the present day, largely because they were among the few men in the community with a higher education, sharing this distinction with the minister. They often engaged in the prevailing occupation of the day, namely, farming, partly as an avocation and partly to supplement the often meager income from the practice of medicine. Two of the New Hampshire signers of the Declaration of Independence were physicians, Josiah Bartlett and Matthew Thornton.

Dr. John Rogers, of Plymouth, one of the incorporators of the New Hampshire Medical Society, was a conspicuous example of public service in many fields. He was the first college-bred man in Plymouth, first postmaster, member of the first board of school supervisors, one of the founders of the Academy and register of deeds for Grafton County; he was frequently called on to preside at town meetings, and was said to have supported every public enterprise with zeal and conspicuous activity.

The old saying that history repeats itself, however, is well exemplified in the person of our present governor, who combines dairy farming, manifold civic and social activities, and a distinguished political career with the practice of medicine.

In the light of modern medical science, many of the practices of this period seem absurd. Yet many of our methods may seem just as absurd to

future medical generations. Those of us who have practiced medicine forty years or more can recall certain treatments, such as the cold-air cure for pneumonia, indiscriminate ovariectomy and the toilet of the peritoneum in cases of general peritonitis, all of which have been discarded. It is probable that the removal of tonsils, doubtless the commonest operation today, will be much modified in time to come, and some of the shotgun vitamin therapy so popular today may seem absurd to our medical successors.

The doctor of 1791 lacked the advantages of the modern diagnostic and therapeutic armamenta-

rium; he was obliged to depend almost entirely on symptoms for diagnosis and prognosis, and was a most careful observer, as attested by current medical literature. Yet he was a resourceful person, and I wonder how some of our Class A medical-school graduates would fare today if obliged to depend on their five senses as our medical forebears were.

5 South State Street

## INSULIN RESISTANCE IN A CASE OF DIABETES MELLITUS AND CHRONIC LYMPHATIC LEUKEMIA\*

### Report of a Case

J. ELLIOT LEVI, M.D.,† AND HENRY T. FRIEDMAN, M.D.‡

BALTIMORE

CASES of severe insulin resistance have been reported by many observers.<sup>1-7</sup> The maximum dose reported to date was given by Wiener<sup>8</sup> in 1938. He administered 3250 units in twenty-four hours to a fifty-eight-year-old man. No explanation for this phenomenon of insulin resistance has yet been given, although several have been suggested. We report the case of a diabetic and also leukemic patient who received 4000 units of insulin a day on four successive days. A thorough search of the literature has failed to reveal the administration of an insulin dose of this magnitude. Furthermore, the association of diabetes mellitus and leukemia has been reported in only 14 cases.<sup>9, 10</sup> Additional evidence for the infrequency of this occurrence is found in the files of the Sinai Hospital, where in over 83,000 admissions, from 1922 to 1940, these diseases were diagnosed as associated on only two occasions prior to the present case.

This case is reported, not with any hope of explaining the mechanism of insulin resistance, but because we believe this to be the largest dose of insulin ever administered to a human patient and because this is the first case of insulin-resistant diabetes in the presence of leukemia.

#### CASE REPORT

H. G., a 64-year-old Jew, was admitted to the Sinai Hospital on February 17, 1940. The patient had suffered

from hypertensive cardiovascular disease for years, and had been deaf for many years. Two years before admission, he had a complete hemiplegia. The family history was noncontributory. The illness for which the patient was hospitalized began 1 week before admission with malaise, fever and cough.

On admission, the temperature was 102.8°F., the pulse 120, and the respirations 38. The blood pressure was 200/100, and the weight 128 pounds. Physical examination revealed a moderately well-nourished and well-developed man who was acutely ill, dyspneic and cyanotic but fairly alert and co-operative. There were herpes labialis and signs of consolidation of the lower lobe of the left lung. The heart was slightly enlarged, with a loud first sound at the apex and an accentuated aortic second sound. There was marked peripheral arteriosclerosis. The abdomen was full, distended and tympanitic throughout. The liver edge, which was not tender, was palpable four fingerbreadths below the right costal margin; the spleen was palpable one fingerbreadth below the left costal margin. Multiple joints showed evidence of chronic hypertrophic arthritis. There was a residual left hemiplegia and right facial weakness. The eyegrounds were obscured by cataracts. There was no lymph-node enlargement, but the epitrochlear nodes were bilaterally enlarged. The blood showed a red-cell count of 4,240,000 with a hemoglobin of 12.6 gm., and a white-cell count of 94,700 with 20 per cent adult and 26 per cent young polymorphonuclear neutrophils, 51 per cent lymphocytes and 3 per cent monocytes. The urine showed a +++ test for sugar, but neither acetone nor diacetic acid. A serologic test for syphilis was negative. The blood urea was 62 mg. and the uric acid 4.8 mg. per 100 cc.

The patient was treated with sulfapyridine and insulin, as well as with supportive measures. The temperature fell to normal in 60 hours, and he made an uneventful recovery from the pneumonia. The blood sugar fell from the admission level of 352 mg. to 192 mg. per 100 cc. in 15 hours with the administration of 15 units of insulin, and the patient was regulated on a diet of 100 gm. carbo-

\*From the Medical Service, Sinai Hospital, Baltimore.

†Formerly, resident in medicine, Sinai Hospital.

‡Formerly, intern in medicine, Sinai Hospital.

hydrate, 60 gm. protein and 60 gm. fat, with 18 units of regular insulin twice a day. On this regime, there was no glycosuria, and the fasting blood-sugar level was 89 mg. per 100 cc. Further study of the blood revealed total white-cell counts varying from 77,000, with 76 per cent lymphocytes, to 230,000, with 86 per cent lymphocytes. At no time were any blast forms seen. The platelet count was 194,000. The basal metabolic rate was +20 per cent. A bone-marrow aspiration was interpreted as typical of chronic lymphatic leukemia. The patient was discharged on March 21, with diagnoses of lobar pneumonia, hypertensive cardiovascular disease, with cardiac dilatation and hypertrophy, old hemiplegia, chronic lymphatic leukemia and diabetes mellitus.

The patient was readmitted on August 26. Since March, he had been fairly well until 4 weeks before admission, despite a gradual weight loss of 28 pounds and the development of a painful, indolent ulcer on the left heel. Weekly fasting blood-sugar determinations during the interval averaged about 128 mg. per 100 cc. On July 31, the patient noted polydipsia and polyuria. The fasting blood-sugar level at this time was 330 mg. per 100 cc. He was treated at home with orange juice and insulin, and within a few days, the blood-sugar level was 98 mg. per 100 cc. He was then returned to his previous diet. On August 17, he showed a +++ test for glycosuria and received 130 units of insulin. Within 24 hours, the urine showed a ++ test for sugar. On August 18, the insulin was increased to 150 units a day; it was kept at this level for 5 days. This only partially controlled the glycosuria. On August 22, the fasting blood-sugar level was 350 mg. per 100 cc., and the patient was again placed on four feedings of orange juice, with four doses of insulin during each 24 hours. On August 24, the urine was sugar free, and the blood-sugar level 250 mg. per 100 cc. On August 25, the patient received 255 units of insulin in four doses, and the urine showed a + test for glucose in the evening. On the day of admission, the fasting blood-sugar level was 225 mg. per 100 cc., and the urine showed a ++ test for sugar. Physical examination on admission revealed a temperature of 99°F., a pulse of 100, and respirations of 20; the blood pressure was 210/65. The patient was poorly nourished and appeared chronically ill. There was generalized lymph-node enlargement. The fundi were poorly visualized, but the disks appeared normal; there were arteriosclerotic changes in the vessels, but no evidence of retinopathy. The tonsils were enlarged, without evidence of infection. There was a chronic superficial ulcer on the posterior aspect of the left heel. Otherwise, the physical findings were the same as those on the first admission. The blood showed a red-cell count of 4,500,000 with a hemoglobin of 14.5 gm., and a white-cell count of 63,000 with 8 per cent neutrophils, 4 per cent eosinophils and 88 per cent lymphocytes. The blood urea was 37 mg. per 100 cc., the blood uric acid was 5.2 mg. per 100 cc., and the basal metabolic rate was +31 per cent. The blood-sugar level was 327 mg. per 100 cc., and the carbon dioxide combining power was 53.2 vol. per cent. The urine showed a + test for albumin, a +++ test for sugar, a ++ test for acetone and no diacetic acid. Stereocroentgenograms of the skull revealed no abnormalities. A hip-puric acid test for liver function showed 100 per cent efficiency.

Except for congestive heart failure during the last week and persistence of the painful ulcer on the left heel, the patient was practically asymptomatic. He showed a daily evening rise of temperature to 101°F. The white-cell

count varied from 61,000 to 225,000, with 85 to 95 per cent lymphocytes, and an occasional blast was seen. The eosinophil count varied from 2000 to 8000, and on one occasion rose as high as 18,000. On September 2, the patient developed a rather marked hematuria, which persisted throughout this admission and was followed by a moderate anemia, for which the patient was transfused with 350 cc. of blood.

On admission, the patient was given his old diet of 100 gm. carbohydrate, 60 gm. protein, 60 gm. fat. During the first 24 hours, he received 100 units of insulin, but the blood sugar remained above the admission level. For the next 48 hours, 2080 units were required. At the end of this period, the blood-sugar level was 109 mg. per 100 cc., and the patient developed hypoglycemia, with symptoms; insulin was omitted for 16 hours. Beginning August 29, insulin was gradually increased for 15 days until the patient received 4000 units in 24 hours, 800 units of which were protamine zinc insulin. He received this dose for 4 days, during which the blood-sugar levels varied between 200 and 450 mg. per 100 cc. On September 17, the amount fell to 66 mg. per 100 cc., and the patient again developed symptoms of hypoglycemia. The insulin dosage was reduced, and for 3 days he received from 1100 to 1300 units a day, the blood-sugar levels varying from 66 to 356 mg. per 100 cc. On September 20 and 21, 3100 units of insulin were administered each day, and the amounts of blood sugar ranged from 344 to 476 mg. per 100 cc. On September 22, the patient had a marked hypoglycemic reaction after receiving 2000 units, which was treated with intravenous glucose. During the next 24 hours, the blood-sugar levels averaged about 60 mg. per 100 cc., and he received 300 units of insulin. For the next 8 days, the insulin requirements gradually rose again, until on September 30 and October 1, he received 3200 units a day, with blood-sugar levels ranging from 400 to 500 mg. per 100 cc. Another hypoglycemic phase ensued for 4 days. Insulin was withdrawn for 96 hours, and carbohydrate administered by mouth and vein. This was the only occasion on which the patient developed generalized hypoglycemic convulsions. On October 4, he began to show signs of congestive cardiac failure. On October 7, the hypoglycemia ceased, and the blood sugar began to rise again. Insulin was administered in moderate doses, but despite this and other treatment, acidosis supervened and congestive cardiac failure progressed. The patient died on October 11, 6½ weeks after admission. Permission for autopsy was not obtained.

## DISCUSSION

This case is of interest because of the size of the insulin dose and the coincidental occurrence of leukemia.

The patient received 76,195 units of insulin in forty-seven days, or an average of 1621 units every twenty-four hours. During this entire period, he was under hospital conditions and at complete bed rest. The insulin was obtained from several different sources, and included 1280 units of zinc insulin crystals and 9950 units of protamine zinc insulin. Insulin from different sources was used to exclude the possibility of an inactive lot of insulin and of allergic reactions to animal insulins.

Two recent articles<sup>11, 12</sup> have thoroughly reviewed the subject of insulin resistance and the

many suggestions that have been made concerning its mechanism. The general conclusion in both these articles is that nothing is known that will satisfactorily explain such a high degree of insulin insensitivity.

Root and Carpenter<sup>13</sup> have approached the problem of insulin resistance by the determination of respiratory quotients to study the metabolism of glucose in diabetic patients under various conditions. In uncontrolled diabetes, the fasting respiratory quotient is low, but rises rapidly to normal

kemia, persistent eosinophilia and an indolent ulcer of the left heel.

The increase in insulin requirement, occasioned by complicating infection, never reaches the proportions attained in this case even in the presence of severe acute infections, and this superficial chronic ulcer can therefore be excluded as a possible cause of the insulin resistance.

The eosinophilia is worthy of comment only because several cases previously reported<sup>14, 15</sup> exhibited insulin resistance associated with allergic

FIGURE 1. Summary of Clinical Data.

after a few days of insulin therapy. Patients under insulin treatment show a rise in the fasting level of the respiratory quotient if the amount of carbohydrate in the diet is increased. In cases of insulin resistance in which insulin efficiency is seriously impaired, the respiratory quotient can be raised to a normal level if sufficient insulin is given. This indicates at least a partial correction of the disturbed carbohydrate metabolism. In addition, Root and Carpenter point out the cyclic character of insulin resistance, which this case demonstrates so well.

Although no necropsy was performed on this patient, clinical study revealed no evidence of pituitary or hepatic dysfunction. The only complicating conditions that might have been related to the insulin insensitivity were chronic lymphatic leu-

kemia. There was no other evidence of allergic reaction to insulin in the present case, and no definite correlation between the insulin dose and the eosinophil level.

Review of the 14 reported cases of associated diabetes mellitus and leukemia reveals 4 cases of chronic myeloid leukemia, 8 cases of chronic lymphatic leukemia, 1 case of acute myeloid leukemia and 1 case of monocytic leukemia. The 2 patients previously observed at the Sinai Hospital had chronic myeloid leukemia.

The association of insulin-resistant diabetes and leukemia raises the interesting possibility that the increase in blood leukocytes may have some effect in reducing the efficiency of insulin. In 1933, Bürger and Kohl<sup>16</sup> demonstrated the presence of

an anti-insulin substance in the leukocytes of leukemic blood. This substance possessed a trypsin-like activity. Several observers have suggested the presence of an anti-insulin substance in the blood or tissues of leukemic patients. Although no attempt was made to demonstrate the presence of insulin inactivating substances in this case, this mechanism is mentioned as a possible explanation. Against this hypothesis is the absence of insulin resistance in any of the previously reported cases of diabetes associated with leukemia.

### SUMMARY

A fatal case of extreme insulin-resistant diabetes associated with chronic lymphatic leukemia is presented. Seventy-six thousand, one hundred and ninety-five units of insulin were administered in forty-seven days. On four successive days, the patient received 4000 units in each twenty-four hours.

## MEDICAL PROGRESS

### LEUKEMIA: AGRANULOCYTOSIS\*

HENRY JACKSON, JR., M.D.†

BOSTON

#### LEUKEMIA

WINTROBE and Mitchell<sup>1</sup> once more, and very properly, emphasize the facts that any organ of the body may be involved in the leukemic process and that the initial symptoms of leukemia may therefore be of the most varied sort. These authors write, "Such different disorders as acute thyroiditis, osteomyelitis, tuberculosis, pelvic tumor, subacute bacterial endocarditis, infection of the eye, breast tumor, gallbladder disease, coronary thrombosis, paroxysmal tachycardia and brucellosis were considered when the patient was first observed because the clinical pictures were so suggestive of these diseases." To this list could be added many more conditions—especially, obscure oral sepsis, rheumatic fever and acute appendicitis. Most of their cases were examples of

acute or subacute leukemia. However, the protean character of the chronic as well as the acute leukemias and of the leukemoid states can scarcely be overemphasized. Without a full appreciation of the vagaries of these conditions, the proper diagnosis may be missed when it could otherwise be easily made.

The bone changes seen in patients with acute leukemia are again stressed by Mendl and Saxl,<sup>2</sup> who described the following: a local proliferation in the bone marrow, with erosion of the bone trabeculae and subsequent cavity formation; periosteal proliferation; and increased bone formation about the cavities mentioned above. Such changes are particularly apt to be seen in children; they are uncommon in adults. Their detection may lead to a correct diagnosis of leukemia in cases with atypical blood pictures; on the other hand, such lesions may give rise to symptoms closely simulating those of rheumatic fever and may therefore lead the clinician astray unless he is aware of their true significance.

All articles in this series will be published in book form: the current volume is *Medical Progress: Annual, 1940* (Springfield, Illinois. Charles C Thomas Company, 1941. \$4 00).

\*From the Second and Fourth Medical Services (Harvard) and the Thorndike Memorial Laboratory, Boston City Hospital, and the Collis P. Huntington Memorial Hospital.

†Assistant professor of medicine, Harvard Medical School; associate physician, Collis P. Huntington Memorial Hospital.

Moloney<sup>3</sup> once more emphasizes the importance and frequency of mouth lesions in acute leukemia. This aspect of leukemia is of great significance to the oral surgeon and the dentist, as well as to the internist; in fact, some oral surgeons always do a complete blood study on any patient with an obscure oral lesion—a very wise precaution.

It is now increasingly well recognized that many pathologic conditions may give rise to hematologic pictures very closely similar to those of true leukemia,<sup>4</sup> and recently Jackson, Parker and Lemon<sup>5</sup> have described a series of cases that from both a clinical and hematologic viewpoint resemble either hemolytic anemia or chronic myelogenous leukemia. It was not the intention of these authors to define and describe a new disease but rather to delineate a clinical and pathologic syndrome that was, in their opinion, worthy of separation from the hemolytic anemias and the leukemias simply because the usual therapy of these conditions—splenectomy and irradiation, respectively—usually brought about speedy death in the disease that they describe as agnogenic myeloid metaplasia. The condition runs a chronic, comparatively asymptomatic course. The spleen is often greatly enlarged. A past history of mild polycythemia may be elicited. The red cells are frequently abnormally fragile, and show a marked variation of size and shape. Nucleated red cells out of proportion to the degree of anemia present are often seen, and there is almost always a definitely leukemoid type of white-cell reaction. The bone marrow may be fibrotic, aplastic, normal or hyperplastic; it never shows the characteristic features of true leukemia. The fibrotic spleen shows scattered areas of erythropoiesis and myelopoiesis, but the Malpighian corpuscles are for the most part intact, and the diffuse sheetlike infiltration so commonly seen in leukemia is absent. The relation of this syndrome to true leukemia, hemolytic anemia, polycythemia and benzol poisoning must remain *sub judice*. It is possible that certain industrial solvents play a role in its initiation.<sup>6</sup>

The treatment of acute and chronic leukemia still remains unsatisfactory.

It is the general consensus that patients suffering from acute leukemia should be treated for symptoms only.<sup>7</sup> As Lucia<sup>8</sup> states: "It is more valorous to be conservative in the treatment of acute leukemia. It is rarely benefited by any sort of treatment." I heartily agree: with the obvious reservation that symptomatic treatment—especially transfusion to combat bleeding—is clearly indicated so long as it is possible to alleviate the patient's distress by nonspecific measures.

Those agents commonly used to combat chronic leukemia are either useless or dangerous.

For patients with chronic leukemia,—of whatever sort,—irradiation still remains the treatment of choice. Lucia<sup>8</sup> has admirably summarized present-day knowledge—or lack of it—in this respect. He believes that treatment should be considered: when the leukocyte count is over 200,000; when the effects of mechanical pressure produce symptoms; when there is a marked and progressive anemia; when weight loss is a prominent factor, and especially when it is due to gastrointestinal dysfunction; when there are hemorrhagic manifestations; when the temperature remains elevated; and when the basal metabolic rate is high. He expressly states, "Do not treat a leukocytosis." I take this to mean that he would not treat a patient with leukemia who had a high white-cell count but who had no complaints whatever. This seems to be a conservative view. Unfortunately, there are few such patients—particularly in the myelogenous group. It has been for a long time my own opinion that any patient with chronic leukemia who has any symptoms properly referable to the disease—be they ever so slight—should be treated. The majority of those interested in this field agree on this point. On the other hand, it is the sincere and carefully considered opinion of some workers that *completely* asymptomatic cases of chronic leukemia do not need specific treatment.

There is a growing belief that the smallest dose of x-ray that will produce the desired result is the best. Dowdy and Lawrence<sup>9</sup> believe that each case should be individualized and that initially from 25 to 50 r should be directed to the spleen, to the involved nodes or to quadrants of the body, and that further treatments should be given as indicated by the patient's course. These investigators give daily doses as required but properly warn that a rapid decrease in the white-cell count necessitates an interruption of the treatment until the count has become stabilized. This latter point needs especial emphasis. The routine, uncontrolled continuance of any form of x-ray therapy may result in a dangerous degree of leukopenia—even death. One cannot predict in advance how much irradiation will be required, and it may seriously be questioned whether daily doses—even though small—are entirely safe in all cases. The white-cell count in patients with leukemia occasionally falls with great rapidity days or weeks after the last treatment, even though this was as small as 25 or 50 r.

Murphy,<sup>10</sup> writes, "The most obvious and serious fault [of treatment] appeared to be that of

allowing the patient to develop repeated relapses during which the disease has progressed followed by intensive treatment at a time when the general condition is poor." That practically every investigator in this field has done his best to avoid this sequence of events need hardly be pointed out. Murphy goes on to state that there is a "belief held by many clinicians that the patient with chronic leukemia is not in better condition with a low than with a high leukocyte count." "It is quite obvious," he says, "that with the method of therapy often employed such might be the case. Massive x-ray dosage is applied over the spleen at a time when the patient is weakened after suffering from anorexia and nausea and with a high leukocyte count." "Massive x-ray dosage," in the true sense, should *never* be used in patients with leukemia, and treatment should always be instituted as soon as symptoms of whatever sort appear. Treatment should *never* be withheld until the patient's general condition is poor and his efficiency low. To do so is to court disaster. Few students of the disease would be so bold. Murphy, himself, advocates 50 to 60 r at a time to the entire body by the spray technic. This general scheme of treatment seems reasonable. Yet 50 r spray may in certain cases be too large a dose, and certainly Reznikoff<sup>11</sup> is correct when he warns that "it is important to determine therapy not on any routine but on what the patient shows at the particular time and how the patient responds to the particular therapy at a time."

It is possible that spray irradiation to the entire body at appropriate intervals (weeks), with due regard for the patient's signs and symptoms and his total red-cell and white-cell counts, is the most effective treatment today. It may further be necessary to give regional treatments to the spleen or greatly enlarged lymph nodes; for the latter are not infrequently entirely unaffected by spray irradiation even though the total white-cell count is greatly reduced and the patient's general condition apparently improved.

It is curious that so few investigators refer to the red-cell count or its bearing on the general situation. The problem of leukemia—with certain obvious limitations—resolves itself into the maintenance of a reasonably normal red-cell count rather than the reduction of the white-cell count to certain arbitrary levels. The inestimable value of transfusions in chronic leukemia is seldom stressed. It should be. More than one patient has been kept alive and at his usual work for long periods by repeated transfusions, without irradiation of any sort. Furthermore, no patient should be given irradiation therapy if marked anemia is present,

even though in general such treatment, by partially freeing the bone marrow of the abnormal white cells, may have a beneficial effect on erythropoiesis. Several transfusions may be necessary to raise the red-cell count to a level at which irradiation may be safely and beneficially given.

The role of radio-phosphorus in the treatment of leukemia has yet to be fully evaluated. It is clear that such substances should be tried under proper conditions by physicians conversant with the disease. It is equally clear that this form of therapy should not yet pass into general use or be regarded as definitely superior to other forms of irradiation. Lawrence<sup>12</sup> concludes that it is too early "to estimate fairly this form of therapy." Erf, Tuttle and Lawrence<sup>13</sup> give a very complete discussion of the use of radio-phosphorus in leukemia and consider that it "is as effective as other types [of treatment] in general use, can be easily administered orally or intravenously, produces no nausea, weakness or anorexia . . . and the results are sufficiently encouraging to warrant intense investigation." One might perhaps substitute the word "critical" for "intense." According to these authors, acute leukemia does not respond any better to radio-phosphorus than to any other form of therapy.

#### AGRANULOCYTOSIS

It is now common knowledge that the great majority of cases of agranulocytosis are secondary to some drug, but I am inclined to agree with Drevierman and Gardner<sup>14</sup> that some are truly idiopathic. Furthermore, it has long been recognized that severe neutropenia indistinguishable from the classic agranulocytosis may be secondary to overwhelming sepsis. In practice, it is difficult, if not impossible, to distinguish between idiopathic agranulocytosis and the leukopenia associated with certain drugs, overwhelming sepsis and industrial poisons. The term "agranulocytosis," as used in this article, is therefore not restricted to the classic definition, but includes states of extreme leukopenia and neutropenia associated with the above-mentioned conditions.

Aminopyrine is now less often a provocative cause, for the simple reasons that the dangers of this drug have become rather widely appreciated and that the sale of the drug is limited by law, but it must be remembered that aminopyrine may be an ingredient of many of the lesser known sedatives and analgesics, and one should be extremely cautious before administering such therapeutic agents unless their composition is definitely known and attested. Several fatal cases of agranulocytosis have followed the administration of Causa-

lin,<sup>15, 16</sup> and without much question many more such cases due to similar drugs of uncertain composition have occurred but have not been reported.

Preparations containing gold are an occasional cause of agranulocytosis. This subject has been recently reviewed by Anderson and Palmer.<sup>17</sup> It should be remembered that some of the pathologic states for which gold salts are administered may in themselves be attended by severe and perhaps fatal leukopenia.

With the ever-increasing use of the sulfonamide compounds, an increasing number of cases of agranulocytosis are directly traceable to these drugs.<sup>18-22</sup>

In a series of personally collected cases, 109 followed the use of some drug. Thirty-four followed sulfanilamide, 8 sulfapyridine, 39 aminopyrine, 7 Allonal and 4 Causalin. In decreasing frequency, the following drugs were apparently causative: Cibalgine, Acetanalid, Amidophen, cinchophen, Amytal Compound, Bismarsen and neocinchophen. It is probable that any of the sulfonamide compounds may cause agranulocytosis; hence, the disproportionately large number of cases that are reported after sulfanilamide is perhaps due to the fact that this drug has, so far, been more widely used than any other of the series. Hadler<sup>23</sup> reports a case apparently due to Allurate; the patient recovered following the use of Pentnucleotide and Reticulogen. This single case report raises the serious question of whether agranulocytosis may not be brought on by barbiturates, heretofore considered blameless.

It is essential to remember, as Rinkoff and Spring<sup>21</sup> point out, that fatal agranulocytosis may follow even small doses of any of the incriminated drugs, and all should therefore be used with the greatest caution. I agree with these authors that such therapeutic agents should seldom be used prophylactically, and it may seriously be questioned whether aminopyrine should ever be used except as an analgesic in patients suffering from incurable disease.

The treatment of agranulocytosis still remains a matter of debate. Forkner<sup>24</sup> appears to regard all forms of therapy as useless. Such pessimism does not favor the acquisition of further data regarding the therapeutics of a disease admittedly fatal in some 70 per cent of the cases. On the other hand, Goldhamer, Sturgis and Bethell<sup>17</sup> write: "We do not agree with Forkner in labelling as useless all forms of treatment which have been suggested for agranulocytosis. It is . . . [our\*] opinion that there does exist evidence which sug-

gests strongly that pentnucleotide and blood transfusions are superior to other forms of therapy and should be employed in all cases." Others<sup>14</sup> recommend Pentnucleotide and yellow bone marrow, both of which agents, in their opinion, play a role in the maturation of the white cells. Strong,<sup>25</sup> discussing 3 cases of granulopenia apparently due to infection, states:

Although the discontinuance of the therapeutic agent [sulfonamide compound] is probably the only measure necessary when the granulocytes reach a low level, pentnucleotide appears to accelerate the rate of recovery of the bone marrow, and this drug may prove to be a useful therapeutic addendum for us with young patients. A combination of attempts to control the infection, discontinuance of drugs which may affect [adversely] the bone marrow, the use of frequent transfusions and the administration of pentnucleotide seems the logical form of treatment.

The question of the administration or continuance of the sulfonamide compounds in the presence of extreme leukopenia must be a matter to be decided in each case. Three points, however, seem clear. Firstly, if the agranulocytosis is patently or probably due to the drug, the latter should be summarily stopped. Secondly, if the agranulocytosis is obviously caused by an infection ordinarily amenable to treatment with the sulfonamide compounds (for example, pneumococcal pneumonia), these therapeutic agents should be immediately started together with such other measures—for example, Pentnucleotide—as the physician in charge believes may help restore the white-cell count to normal levels. Thirdly, the mere withdrawal of the offending drug does *not* always suffice to restore the white-cell picture to normal, especially if the leukopenia and granulocytopenia have been extreme, in spite of a rather general belief that withdrawal is sufficient. Such optimism is based largely on reports of cases with moderate leukopenia (for example, 3000 white cells, of which 20 per cent were polymorphonuclear neutrophils). In 72 personally collected cases of extreme agranulocytosis (without anemia of moment) due to sulfonamide compounds or other drugs, recovery occurred in but 30 per cent of those in which withdrawal of the drug was the only measure taken. In 26 similar cases in which the drug was withdrawn and adequate amounts of Pentnucleotide (40 cc. a day) were given, recovery occurred in 66 per cent. The series is small, but the results are suggestive. In any event, daily white-cell and differential counts should be done on all cases suspected of having agranulocytosis, and energetic measures should be immediately started if the diagnosis is established.

\*Personal communication from Dr. Cyrus C. Sturgis correcting a misprint in the article.

If one has faith in any of the therapeutic measures advocated, the value of prompt diagnosis and treatment cannot be overemphasized. If one maintains a robust pessimism, the acquisition of hematologic data is purely of academic interest. It is my own belief—and it is shared by others—that all patients under treatment with any drug that has been incriminated should have frequent blood-cell and differential counts and that if the total granulocyte count is found to be very low, immediate treatment should be instituted—whether one chooses Pentnucleotide, frequent transfusions, yellow bone marrow or a combination of two or more treatments. The same principle holds true of patients with a severe sore throat, perhaps the commonest initial symptom of agranulocytosis. It is furthermore imperative that treatment should be intensive—with Pentnucleotide, no less than 40 cc. a day should be given and continued until a favorable response has occurred or until it is apparent that no benefit will accrue.

It is perhaps worth pointing out that those measures designed to combat agranulocytosis will not benefit patients with aplastic anemia or those with aleukemic leukemia, both of which conditions may be confused with agranulocytosis. But it is equally important to note that these therapeutic agents can do no harm in such cases. If there is the slightest doubt concerning the diagnosis, the patient should be treated as a case of agranulocytosis.

## CASE 27511

### PRESENTATION OF CASE

A dirty six year-old physician was admitted to the hospital because of a long history of recurrent pneumonia," treated in several different outside hospitals

Twenty two years before entry, the patient had epidemic influenza, with probable left sided pleurisy After recovery, he was in good health for six years Then, while in college, following an upper respiratory infection, he developed pneumonia of the left lower lobe, which resolved slowly over a period of three months From that time on, he felt "rundown" Fifteen years before entry, while in his first year at medical school, he again had an extended attack of "left lower lobe pneumonia," following an upper respiratory infection, there was slight hemoptysis at the onset In the later stages of the illness, the patient coughed up pus Several chest taps failed to reveal fluid A rib resection was considered but not under taken He was fairly well for about three months, only to have another similar episode, a productive cough remained after the other symptoms had cleared He was therefore bronchoscoped, and an "obstruction" removed from the bronchus to the left lower lobe Microscopic sections were said to have shown bronchiogenic carcinoma or granuloma Subsequent bronchoscopies were performed at lengthening intervals, with occasional application of iodine to the site of the former obstruction This course of treatments brought marked improvement, and the patient was quite well for several years In a check up examination two years later, an instillation of lipiodol was said to have shown some left lower lobe bronchiectasis, but no obstruction A bronchoscopic check examination, ten years later, was considered essentially negative During this long interval, the patient remained quite well Then, seven months before entry, he again went through the sequence of upper respiratory infection, slight hemoptysis and "left lower lobe pneumonia," lasting about a month After the acute phase of the illness, he remained somewhat tired A roentgenogram of the chest showed the heart shifted to the left, and the lung fields fairly clear About

four months before entry, another respiratory infection was followed by slight hemoptysis and left lower lobe consolidation The temperature spiked to 102°F for about a month The patient was bronchoscoped at least ten times, with removal of a left lower lobe obstruction," and subsequent drainage of pus Convalescence was gradual, with reduction in the temperature and the amount of sputum coughed up Most of the 30 pounds of weight lost during the active phase of the illness was regained In the few months preceding entry, the patient felt fairly well, between recurrent bouts of fever up to 101°F, which lasted four or five days and were associated with severe night sweats The sputum averaged 3 or 4 tablespoonfuls a day

The family history was not of interest, except that the patient was one of twins Prior to the onset of his series of illnesses, he had been quite athletic and active He said that he was "allergic" to a number of substances, including iodides

On admission, the patient appeared strong and well developed, with a moist skin that seemed pale although tanned The trachea and heart were shifted to the left The heart was otherwise normal There was dullness posteriorly over the area of the left lower lobe, with bronchial breathing, increased whispered and voice sounds, and decreased tactile fremitus There were no rales The diaphragm was high on the left side, but showed good excursions on the right The abdomen was normal The fingernails were slightly ridged, but were not clubbed

The temperature was 98.6°F, the pulse 78, and the respirations 20 The blood pressure was 134 systolic, 74 diastolic

Examination of the blood showed a red cell count of 5,050,000 with 15.3 gm hemoglobin, and a white cell count of 11,800 with 68 per cent polymorphonuclears The blood Hinton reaction was negative The serum protein was 5.6 mg per 100 cc The urine was normal Culture of the sputum grew alpha hemolytic streptococci

A roentgenogram of the chest showed slight elevation of the left diaphragm, with limited paradoxical motion The left lower lung field was evenly dense, up to the level of the third rib anteriorly There was questionable narrowing of the left lower lobe bronchus The left hilus was placed low The mediastinum was displaced markedly to the left, with a shift in that direction on inspiration The upper part of the left lung field was bright, and the right lung field was clear Another roentgenogram of the chest, five days later, was essentially similar

An electrocardiogram was normal except for a tendency to slight left axis deviation

On the seventh hospital day, an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. RALPH ADAMS\*: The outstanding characteristic of this history is the symptomatology associated with recurrent episodes of localized pulmonary infection over a sixteen-year period in a young man who was otherwise in good health. Since chronic pulmonary infection is always a suppurative process, differential diagnosis should be concerned with only two problems: the nature of the infection and its primary cause. I shall discuss the type or nature of the infection before its cause, since that is the sequence in which pulmonary disease is considered clinically, the presenting symptoms being based on an etiology that is rarely, in itself, manifest.

The influenza from which the patient suffered at the age of fourteen, twenty-two years before entry, during the great influenza epidemic of 1919, I am inclined to accept as diagnosed because it is not statistically unlikely that he should have had the disease in that year, and because his subsequent good health for the next six years seems to classify it as an isolated case of acute infection and recovery. Then, at the age of twenty, sixteen years before entry, he had an attack of so-called "left-lower-lobe pneumonia," which required three months to resolve, and left him rundown. Pneumonia that requires three months to resolve either has been complicated by unrecognized empyema or is not true pneumococcal pneumonia. Barring empyema, the cause is more likely to be lung abscess or pneumonitis secondary to bronchial obstruction.

A year later, the patient had a second extended attack of left-lower-lobe pneumonia, accompanied initially by hemoptysis and terminally by pus. The common reasons for hemoptysis are categorically easy to state, although selection of the proper reason in a specific case may require much analysis and more or less specialized methods of diagnosis, such as bronchoscopy and the injection of iodized oil. Hemoptysis implies mechanical injury, invasion, ulceration or necrosis of some part of the bronchial mucosa, and may be secondary to a foreign body, a benign or malignant tumor, infections like bronchiectasis and lung abscess, or lack of oxygenation of the tissues from infarcts or advanced mitral stenosis. I must add a small group in which one simply cannot determine the cause of the bleeding. All thoracic clinicians have encountered them. The late appearance of purulent sputum in this case indicates that an infection was instrumental in causing the hemoptysis. Em-

\*Surgeon, Lahey Clinic.

pyema was suspected, and unsuccessful chest taps ensued, undoubtedly done after the misinterpretation of the x-ray shadow of lobar consolidation or collapse as pleural fluid. This is a common error and carries the hazard of producing the disease it is designed to detect. Another common reason why a chest tap may fail to reveal fluid is that the needle is inserted too low in the chest. The next episode, three months later, was followed by a productive cough, and this sign must be added as another bit of evidence in the case that I am building for chronic bronchopulmonary suppuration.

At this time, two years after the onset of the disease and fourteen years before entry, the patient was bronchoscoped, and an "obstruction" removed from the left-lower-lobe bronchus. I am left to guess what the obstruction was, and for the delectation of this audience it is of course hoped that I shall guess wrong. Again, speaking generically, the varieties of bronchial obstruction are easy to classify. They may come only from without or within the patient. If from without, they are, *ipso facto*, foreign bodies; if from within, they are benign or malignant tumors, liquid or inspissated secretions, or stenosing processes secondary to infections or pressure. Here, as in cases of hemoptysis, decision in terms of the individual patient is more difficult than textbook enumeration. I shall discount completely the microscopic report of bronchiogenic carcinoma, which when untreated is incompatible with a subsequent life of fourteen years. In spite of alleged evidence in the literature to the contrary, most tumors with microscopic diagnoses of bronchiogenic carcinoma made in patients found to be alive several years afterward without surgical intervention have proved, on critical review of the slides, to be benign adenomas of the bronchus. The bronchial application of iodine is neither recommended nor believed to be helpful therapy. Iodized-oil instillation two years later in this patient revealed bronchiectasis, and thus completes the data on the nature of the intrapulmonary process.

I shall try to determine the primary cause of this process. Carcinoma has been excluded. Except for the check bronchoscopy some years after the first, I find it troublesome to exclude a benign adenoma, because many of the criteria for adenoma have been fulfilled: there was bronchial obstruction, with repeated slight hemoptyses; there were frequent episodes of pneumonitis; there was proved bronchiectasis peripheral to the observed area of obstruction; and by x-ray films, the heart was shifted toward the lesion. But the obstruction seen at the first bronchoscopy was gone at the

second Adenomas do not disappear, they grow larger, and the extrabronchial growth is often disproportionate to the intrabronchial, causing both intrinsic occlusion and extrinsic pressure. This situation could hardly have been missed. Therefore, I am forced to say that the patient did not have an adenoma, and that the subsequent bronchoscopies were only for removal of pus. Since the iodized oil injection, the second bronchoscopy and, finally, the x-ray films showed no bronchial obstruction at the later date, the possibilities are reduced to inspissated secretion and a foreign body surrounded by inflammatory tissue to explain the obstruction that the first bronchoscopist removed and the pathologist diagnosed as a "bronchiogenic carcinoma or granuloma." I doubt if anyone could mistake a mucous plug for a carcinoma, but organic foreign bodies, particularly, can produce a violent bronchial reaction. I am now left supporting the proposition that the original obstruction removed bronchoscopically was a foreign body that was misdiagnosed, and that all the succeeding illness was a sequel in the irreparably destroyed lung peripheral to the obstruction. It seems that a boy of twenty would know whether he had inhaled a foreign body, and have said so for the record, and here is the weak point in the circumstantial evidence as arrayed. However, I can do no better and shall let the cause of obstruction rest as a foreign body until Dr Mallory discards it.

The physical and x-ray findings in the chest were typical of the pathologic process as postulated—that is, a collapsed chronically infected left lower lobe, with compensatory emphysema of the left upper lobe and a shift of the mediastinal structures and diaphragm. I cannot explain the paradoxical diaphragmatic movements described, unless the patient had had a surgical phrenic paralysis at some time in his therapeutic course.

May we see the x-ray films?

DR AUBREY O. HAMPTON: These are selected films that show marked displacement of the heart to the left. With barium in the fundus of the stomach, one can see that the diaphragm is elevated. There is a shadow that rises in the left axillary line, and the whole lower portion of the left lung is dense. The size and shape of the shadow is not the picture we see in uncomplicated collapse of the left lower lobe. The band of density along the left axillary line is not compatible with simple collapse but is compatible with collapse and pleurisy. Here is another in compatible feature, that is, a shadow at the lung root, which is convex upward. I do not know

the answer to this. Here are dilated bronchi, so that bronchial occlusion is not complete, but there is no other air in the lower lobe.

DR ADAMS: When I started the discussion, I felt insecure in my analysis of the cause of obstruction, which I had based more than I liked on the pathology as reported and as not reported. After seeing these films, I must admit that a benign adenoma of the bronchus is just as likely as an old foreign body, and I really do not know which to place first. I am prepared now to reverse myself. My diagnosis in this case is bronchiectasis, chronic recurring pneumonitis and peripheral pulmonary suppuration with old bronchial obstruction, probably due to a primary benign adenoma.

DR WILLIAM B. BREED: I should like to ask why Dr Adams surrendered the foreign body hypothesis so quickly. Was it entirely on the basis of the x-ray films?

DR ADAMS: Yes, the x-ray film is the most important diagnostic feature in thoracic disease, I believe, and I had not had the benefit heretofore of seeing the films. Having seen them, I should go so far as to say that this is the classic picture of adenoma of the bronchus.

#### CLINICAL DIAGNOSES

Adenoma of left lower bronchus  
Bronchiectasis

#### DR ADAMS'S DIAGNOSES

Bronchial adenoma  
Bronchiectasis  
Chronic bronchopulmonary suppuration

#### ANATOMICAL DIAGNOSES

Bronchial adenoma  
Pulmonary atelectasis  
Bronchiectasis

#### PATHOLOGICAL DISCUSSION

DR TRACY B. MALLORY: It was possible to obtain the old microscopic sections of this patient, and on review of them it was clear to us that this was a so-called "adenoma." On that basis, Dr Edward D. Churchill decided to treat the case with a pneumonectomy. The resected lung showed a large, almost spherical tumor completely filling and absolutely plugging the bronchus to the lower lobe, and producing very marked bronchiectasis, with secondary atelectasis and fibrosis of the surrounding lung tissue (Fig 1). The tumor was large enough to have pressed on and occluded by external pressure the bronchioles running down to the lingula of the upper lobe. The lingula presented a more acute type of pneumonitis, a so

called "drowned-out" lung, without bronchiectasis. These peculiar bronchial tumors were first described as adenomas, which is perhaps not a good term, because they very rarely show any gland formation and an adenoma should be a tumor made up of tumor cells producing glands. The nature of this tumor is still uncertain. The tu-

and a variety of other tumors from time to time show bone-forming stroma. The bone in this case, as in all others that I have studied, seems to be a product of the stromal cells, not of the tumor cells.

X-ray studies of the tumor after its removal clearly showed the calcified bone in the tumor (Fig. 2),

FIGURE 1. Photograph of Half of Resected Lung.

*Note the hemispherical adenoma filling the lower lobe bronchus, the dilatation of bronchi in the lower lobe (to the right of the tumor), with associated atelectasis, and the pneumonitis of the lingula of the upper lobe.*

mors are of very similar appearance, always made up of rather small uniform cells, never showing multinucleated giant cells, and never showing many mitotic figures. The cells are arranged in anastomosing cords or trabeculae, closely similar to so-called "carcinoid tumors" of the intestinal tract. They are not, however, argentaffin like the carcinoid tumors. A feature that has provoked a good deal of interest in recent years has been the finding in many of these tumors of trabeculae of bone. In this tumor, considerable amounts of bone were present.

The finding of bone in these tumors has led to the suggestion that they are mixed tumors. It has also been claimed that cartilage is sometimes found. I have not been impressed with cartilage as a component part of the tumor. They are slightly invasive tumors, and may surround the bronchial cartilages; consequently, the cartilage that one sees may be just an included remnant of the bronchocartilage. The bone might be a product of the tumor. It might also be a metaplastic reaction in the stroma of the tumor, such as we see from time to time in other tumors, but not with the frequency with which such a reaction is seen in this particular group. Fibroids of the uterus, cancers of the breast, adenomas of the thyroid gland

but I should not consider it possible to make it out on the chest plate.

DR. HAMPTON: I cannot see any bone in the area of the tumor. We have not demonstrated

FIGURE 2. X-Ray of Resected Specimen Showing Ossification within the Tumor.

bone by x-ray study in these cases, perhaps because we have not tried hard enough.

DR. MALLORY: This had more than any of our other cases. Possibly, with an overexposed film, you might have been able to show it.

DR. HAMPTON: It is an important point for us.

## CASE 27512

## PRESENTATION OF CASE

A thirty seven year-old weaver was transferred from another hospital because of convulsive seizures for the previous two weeks.

About eighteen months before admission, while fishing, the patient fell and struck his head on the ice. He was unconscious for a very brief period and subsequently had a severe headache. He was in good health for the next six months and then began to lose weight, to be fatigued easily, and to vomit occasionally. After one of the attacks of vomiting, he complained of numbness and weakness on his right side. He had difficulty in forming sentences, and seemed to stumble over his words.

When first seen at the other hospital, eleven months before entry to this hospital, the patient was listless and apathetic. His pupils were equal and reacted normally. The fundi were not remarkable. The neck was slightly stiff. The right arm was completely flaccid, with absent reflexes. The right side of the face was flaccid, and the right leg was weak. Abdominal reflexes were decreased on the left, and absent on the right. The knee jerks were active, the right being greater than the left. The right plantar response was of Babinski type. The rectal temperature was 104.4°F. The blood showed a white cell count of 12,000. The blood Hinton reaction was negative. A roentgenogram of the skull showed a questionable area of increased density low in the left posterior parietal region. When lumbar puncture was performed, the initial pressure was too low to measure, and the fluid was cloudy and faintly xanthochromic. The gold sol curve was 050555000, and the Wassermann reaction was positive. There were 117 lymphocytes per cubic millimeter of fluid; the protein was 500 mg and the sugar 275 mg per 100 cc. Ten days after admission, the patient was discharged free of paralysis.

During the next three months, he received antisyphilitic therapy. Ten months after discharge, he had a bout of fever, associated with difficulty in talking, which cleared up in a few days. Several days later, an apparent convulsion was followed by persistent headache. A lumbar puncture gave bloody fluid under pressure. The following night, he had a severe convulsion and was readmitted to the other hospital.

At this time, the patient was restless and noisy. The temperature was 101°F, the pulse 100, and the respirations 40. The blood showed a white-cell count of 18,800 with 92 per cent polymorphonuclears, and a red-cell count of 4,500,000 with

75 per cent hemoglobin. The urine showed a heavy trace of albumin, with occasional red cells in the sediment. A lumbar puncture the next day yielded 25 cc. of bloody fluid under a pressure equivalent to 450 mm of water. After repeated convulsions, controlled with difficulty by sedation, the patient was transferred to this hospital for study.

The chest and abdomen were normal. The blood pressure was 110 systolic, 60 diastolic. Examination of the blood and urine showed no essential change. There were no motor weaknesses, and no sensory deficiencies, except for impairment of position sense in the left toes. The neck was stiff, and there were positive Kernig reactions. The tendon reflexes were equal and active, with normal plantar responses. The fundi were normal. The speech was hesitant, and there was some loss of recent memory. The attention wandered.

A roentgenogram of the skull showed questionable erosion of the posterior clinoid processes. The shape and size of the sella were normal, and the convolutional markings were of normal prominence. Several apparent intradural areas of calcification lay on either side of the midline, in the frontal region. A roentgenogram of the chest showed no significant changes.

On the third hospital day, two convulsive seizures occurred, preceded by a bout of projectile vomiting. During the second period of convulsions, the patient lay on his right side, his eyes deviating to the extreme right. Half an hour later, there were bilateral, Babinski plantar responses and an almost inexhaustible left-ankle clonus. The pupils were constricted, and the eyes turned toward the left. Respirations were stertorous. After this second seizure, the patient never regained consciousness. A lumbar puncture shortly before death demonstrated grossly bloody fluid, with a pressure of over 200 mm; the gold sol curve was 4453433310, the protein 206 mg. per 100 cc, and the Wassermann reaction negative. Death occurred on the fourth hospital day.

## DIFFERENTIAL DIAGNOSIS

DR. G. COLLET CANER. After reading the whole history, I think it is clear that the head injury which the patient sustained eighteen months before entry to this hospital was not a factor in the case. The physician who took care of the patient when he first entered the other hospital might have had some difficulty in ruling out subdural hematoma as a cause of the symptoms. However, I think it could have been ruled out even at that time. This patient did not have any headache, and a subdural hematoma almost always causes

headache. With a subdural hematoma sufficiently large to cause a hemiplegia, one would certainly expect headache. One would also expect an increase in spinal-fluid pressure, as well as drowsiness or coma, which the patient did not show. The history of the onset of the patient's illness, characterized by loss of weight, rapid fatigability and vomiting, do not suggest a subdural hematoma, which is also made unlikely by the fact that the paralysis of the left arm was flaccid, with absent reflexes. A paralysis caused by a subdural hematoma should be spastic from the beginning. When a palsy due to involvement of the corticospinal motor tract in the brain is of the flaccid type, one expects the lesion causing it to be recent and of sudden onset, as with either hemorrhage or embolism. There were therefore numerous reasons at the time of the first entry for thinking that the numbness and weakness were not due to a subdural hematoma, and there was a strong indication that they were caused by a vascular accident, such as hemorrhage.

If the patient had had a vascular accident at that time, we are interested in its cause. One possibility is hemorrhage into a tumor or in the vicinity of a tumor. The spinal-fluid findings, except for the low pressure and the low sugar, might be explained by brain tumor. The x-ray at that time indicated an area of increased density, low in the left posterior parietal region, which suggests the possibility of meningioma, but one would not expect a meningioma to be associated with hemorrhage. I think that hemorrhage in the region of a tumor could not have been excluded with certainty at the time of the first entry on the basis of the information here given, but the subsequent history is very much against brain tumor, and I think we can now safely rule it out as the cause of the presumed vascular accident.

The usual cause of a vascular accident in a patient of this age, without hypertension, is vascular syphilis. The blood Hinton reaction should be a better criterion of vascular syphilis than the spinal-fluid Wassermann reaction, and the blood Hinton reaction was negative. The positive spinal-fluid Wassermann reaction was obtained on a fluid that was xanthochromic and had a high total protein, and fluids of this character not infrequently give a false-positive Wassermann reaction. The spinal-fluid findings suggest the possibility of a syphilitic meningitis, but certain features are not consistent with this diagnosis. A syphilitic meningitis sufficiently acute to cause only 117 lymphocytes in the lumbar fluid should not cause a total protein much above 50 or 100 mg. instead of one of 500 mg. per 100 cc. Likewise,

any meningitis sufficiently acute to cause such a high total protein should also give a high pressure. The low spinal-fluid sugar is also strongly against a syphilitic meningitis. I therefore believe that the spinal-fluid findings do not favor syphilis and that even at the first entry a diagnosis of syphilis should not have been made on the basis of these findings. The latter part of the history is too malignant for syphilis. I feel safe in ruling it out.

The low spinal-fluid sugar and the high protein suggest a tuberculous meningitis, but the low pressure is strongly against it. The patient also would have appeared sicker if he had had a tuberculous meningitis. The rapid recovery and the long remission of course rule out this diagnosis.

One wonders whether the spinal-fluid pressure might actually have been high in spite of the findings in lumbar puncture. If one does not use a manometer to measure the pressure, one may think that the pressure is low if the fluid drops out slowly, which may happen with a high pressure if the lumen of the needle is partially obstructed. If, however, a manometer is used, the fluid will rise slowly in the manometer and will indicate the true pressure, even though the needle is partially obstructed. The statement that the pressure was too low to be measured indicates that a manometer was used, and we must therefore accept the statement that the pressure actually was low.

It seems to me that the spinal-fluid findings can best be explained by subarachnoid bleeding. The chief objections are the low spinal-fluid pressure and the low sugar. A subarachnoid hemorrhage sufficiently large to cause hemiplegia should give an increased pressure. I think, however, that the low pressure may be explained on the supposition, suggested by the phrase "when lumbar puncture was done," that the lumbar puncture was not done at the time of admission to the hospital, but was done just prior to discharge; if that were so, the subarachnoid bleeding would have occurred ten days or more before lumbar puncture—sufficient time for blood cells to disappear from the fluid and for the fluid to become xanthochromic. It is possible that the total protein might still have been high ten days after the hemorrhage occurred, as a result of the serum that got into the fluid at that time. Subarachnoid hemorrhage would explain the stiff neck, but it would not explain the low sugar very well. Although it is stated in the literature that a low spinal-fluid sugar may be caused by hemorrhage into the subarachnoid space, I do not believe that we have seen it here,—at

least I have not. We expect the spinal-fluid sugar to be normal in these cases. I cannot explain the low sugar in this case, unless it is an error; I cannot use it in the differential diagnosis, and think that we must disregard it. The rectal temperature of 104.4°F., although high, seems best explained by subarachnoid hemorrhage; there is nothing to indicate affection of hypothalamic centers.

If the cause of the aphasia and flaccid paralysis was subarachnoid bleeding, what caused it? A very frequent cause is a small congenital saccular aneurysm. Leakage from such an aneurysm located on the ascending frontal branch of the middle cerebral artery might have caused the signs shown by the patient, and an aneurysm in that vicinity might have been open to surgical treatment. It seems to me that this possibility was sufficient to have warranted surgical intervention.

The patient apparently was quite well for ten months after discharge, and then he had an attack of aphasia associated with a bout of fever. One might explain this by a recurrence of subarachnoid bleeding. Again, the bout of fever is hard to explain, but might be explained on the same basis on which we explained it before. The aphasia might have been caused by a thrombosis, but this would not cause fever. Multiple sclerosis may cause transitory symptoms and a slight rise in temperature, but there is nothing in favor of multiple sclerosis in the rest of the record.

Several days later, the patient had a convulsion followed by a persistent headache, and lumbar puncture then gave a bloody fluid. The bloody fluid is definite evidence of bleeding into the subarachnoid space, and the convulsions can be explained as the result of the cortical irritation caused by the blood. The findings on admission to the other hospital were consistent with subarachnoid hemorrhage, except for the urinary examination, which showed a heavy trace of albumin, with occasional red blood cells. I should not expect a subarachnoid hemorrhage to cause these findings. They suggest the possibility of a bacterial endocarditis, but the rest of the record does not make this at all likely, and I think we can rule this out.

On admission to this hospital, the patient showed findings characteristic of meningeal irritation presumably due to subarachnoid hemorrhage. Since he was not unconscious, he probably did not have a very large hemorrhage at this time and the earlier hemorrhages were also probably not large.

X-ray films in this hospital showed a question of erosion in both posterior clinoid processes and some areas of calcification that do not seem par-

ticularly significant; I should like to see the films, however.

DR. JAMES R. LINGLEY: I think that the erosion of the posterior clinoid processes is questionable. There is no decalcification of the processes, the sella turcica is normal in size, and there is no evidence of destruction; therefore, I think we can probably dismiss that as of no importance. The bones of the vault are rather heavy and dense, but I do not see any definite evidence of hyperostosis to go with a diagnosis of meningioma. The areas of calcification are best seen in the antero-posterior view. They are not linear, as one would expect in an angioma. They are rather flat, and in the lateral view I think you can see that they lie anteriorly. They are probably in the dura and therefore are of no importance. The skull shows no evidence of chronic pressure, and the examination is essentially negative.

DR. CANER: On the third hospital day, the patient had two convulsions preceded by a bout of projectile vomiting, and showed grossly bloody spinal fluid under increased pressure. Evidently, he had had another subarachnoid hemorrhage, which was acute and large. The eyes were turned first to the right and then to the left. That indicates irritation, followed by paralysis of the center for conjugate deviation at the base of the second left frontal convolution, or of the fibers connecting this center with the nucleus of the sixth nerve on the opposite side of the pons. The persistent clonus on the left suggests a lesion on the right. However, there is good evidence that the patient previously had had vascular accidents on the left because of an aphasic attack and because of an attack of flaccid paralysis of the right arm and face associated with aphasia. I should like to explain the last hemorrhage by the same lesion that caused the earlier hemorrhages, although saccular aneurysms are frequently multiple. I do not believe that we can do much more than guess where this last hemorrhage started, but I am fairly confident that it ruptured into the ventricles, as indicated by the small pupils, bilateral Babinski responses, unconsciousness and rapid death.

The assumption that bleeding from saccular aneurysms was responsible for the repeated vascular accidents does not explain some things in the history. It does not explain the red cells and the albumin in the urine or the symptoms at the beginning of the illness, but other common causes for repeated vascular accidents seem unlikely. I have already given reasons why I think syphilis is unlikely. Arteriosclerosis also seems improbable in a man of this age without hypertension. Peri-

arteritis nodosa may cause all the findings recorded in the history. It may cause loss of weight, fatigability and vomiting, symptoms that the patient had at the onset of the illness and are otherwise unexplained. However, very few cases have been reported of repeated attacks of cerebral hemorrhage resulting from periarteritis nodosa. It seems to me that this diagnosis is much less likely to be the true one, even though it would explain the whole case. I therefore conclude that the autopsy will show that this patient died because of a subarachnoid hemorrhage that ruptured into the ventricles and was caused by rupture of a saccular aneurysm. It is my guess that the ruptured aneurysm will be found on the ascending right frontal branch of the middle cerebral artery.

DR. JAMES B. AYER: I know the case, but should like to comment on one statement made by Dr. Caner with which I disagree—that is, that we should pay no attention to the low spinal-fluid sugar. Our laboratory is accurate on this test. Sugar of this amount, 27 mg. per 100 cc., is almost always indicative, or at least suggestive, of infection somewhere in or near the fluid pathways.

DR. CANER: I should agree ordinarily, but this report came from another laboratory. Certainly, I cannot fit the low sugar into my diagnosis.

DR. AYER: Assuming that the other laboratory is correct, I believe we ought to think of infection.

#### CLINICAL DIAGNOSES

Spontaneous subarachnoid hemorrhage.  
Cerebrovascular syphilis.

#### DR. CANER'S DIAGNOSES

Congenital saccular aneurysm.  
Subarachnoid hemorrhage.  
Rupture into the cerebral ventricles.

#### ANATOMICAL DIAGNOSES

Ruptured aneurysm of circle of Willis, with subarachnoid and intracerebral hemorrhage.  
Arteriosclerosis of coronary arteries (slight) and of aorta (slight).  
Retention cyst, right kidney.

#### PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: The significant findings were limited to the head. There was slight generalized arteriosclerosis. The kidneys were perfectly normal. I have no explanation for the albuminuria.

DR. CHARLES S. KUBIK: In some cases of spontaneous subarachnoid hemorrhage, there is an albuminuria, which apparently is not due to any serious kidney disease and which rapidly subsides if the patient recovers. In this case, there was a small aneurysm, about 4 mm. in diameter, in the angle between the right anterior cerebral and anterior communicating arteries. The aneurysm itself was surrounded by a fair amount of old brownish blood clot in which there was some blood pigment indicating that there had been previous bleeding. It had finally ruptured, and the resulting hemorrhage broke through the pia into the left frontal lobe and from there into the anterior horn of the left lateral ventricle. I think it is rather difficult even now to explain the severe right hemiplegia and aphasia that occurred with the first episode, because if there had been a hemorrhage into the left frontal lobe at that time, one would not have expected such a quick recovery. There were no other aneurysms. Although sections of the aneurysm are not yet available, one can be reasonably certain that this is a so-called "congenital aneurysm" and that syphilis can be excluded as an etiologic factor.

## PEACE ON EARTH . . .

IN this critical year of 1941, with still more critical years ahead, we come again to the observance of Christmas, the day of peace on earth, coming so soon after the day of thanksgiving and after the day on which we commemorate the armistice of 1918. The latter was the date to be annually remembered and to be revered in perpetuity, on which warring nations laid down their arms and peace came to brood forever over a world that had learned the futility of force. It was, unfortunately, fittingly titled, for its name suggests the essence of impermanence—according to Noah Webster, a “brief suspension of hostilities by agreement.”

Civilization's great error, certainly of our generation, has been to think of peace as a natural

condition—as the normal state of affairs that immediately succeeds any misunderstanding that may occur in the relations between man and man and between nation and nation. Unfortunately, peace is not like the air (once free) around and above us, which abhors a vacuum and forces it out of existence, or like the waters of the sea (whose freedom was once guaranteed by mutual understanding), which seek and maintain their constant level.

Following the “brief suspension of hostilities” were days of unreality, when the Christian nations, exhausted by a detested, even if triumphant, contest, believed that at last a state of permanent peace had been achieved—a state to be maintained in the council chamber and by Omnipotent guidance, and by little else. We have been awakened from that dream, and our fool's paradise has disappeared. We have come back to the wholesome, if bitter, reality of existence, and an appreciation of the fact that human nature does not change overnight or in a generation—perhaps not in any known period, even as it can be reckoned astronomically. Peace may remain the goal of our ambitions, but it is a higher goal, because we know now that it represents a positive virtue and not a passive state.

Peace is the final objective of our current endeavor; but it must be attained by aggressive action, it must be cultivated and consolidated and fostered, and it must be constantly defended by force—forever, so far as our present minds can reach. When this objective is attained, then can we truly say that, because of our determination to have it so, there may be peace on earth, *to men of good will*.

## PROCUREMENT AND ASSIGNMENT SERVICE

ONE of the greatest problems facing the Government is the procurement of physicians for and their assignment to various governmental positions. Owing to the declaration of war, the demands for medical officers by the United States Army, Navy and Public Health Service will be enormously increased; furthermore, many physicians are needed

by the United States Civil Service Commission and Veterans' Bureau. Industrial and civilian needs, however, should not be neglected, and recent graduates from medical schools should be permitted to continue their educational programs, which demand a minimum of one year of hospital training and at least three or four years for those who are to qualify properly as specialists. The Committee on Medical Preparedness of the American Medical Association anticipated this situation, and on the recommendation of the committee, the House of Delegates passed a resolution last June, which urged the establishment of a governmental agency for the procurement and assignment of physicians.

On October 31, President Roosevelt authorized the Procurement and Assignment Service, a subdivision of the Office of Defense, Health and Welfare Services, Federal Security Agency, under the direction of Administrator Paul V. McNutt. The functions of this service are as follows: to receive from various governmental and other agencies requests for medical, dental and veterinary personnel, to secure and maintain lists of available personnel that show detailed qualifications and to utilize all suitable means to stimulate voluntary enrollment, with due regard for the over-all public-health needs of the Nation, including those of governmental agencies and civilian institutions. According to a suggestion contained in the resolution of the House of Delegates, the board is composed of representatives of the civilian medical profession, as follows: Dr. F. H. Lahey, of Boston, chairman; Dr. H. S. Diehl, of Minneapolis; Dr. J. E. Paullin, of Atlanta; Dr. H. B. Stone, of Baltimore; and Dr. C. W. Camalier, of Washington, D. C., a past president of the American Dental Association. The board has been organized, and at its initial meeting the following subcommittees were appointed: Medical Education, Hospitals, Public Health, Women Physicians, Information, Industrial Health and Medicine, Dentists, Veterinary Medicine and Negro Health.

Although the state of war will undoubtedly result in additional functions and increased responsibility, the wisdom of the appointment of a board of this sort and for this purpose cannot be denied,

and it is hoped that many of the unfortunate orders and recommendations that led to the improper placement of physicians in the services and to unwarranted shortages of physicians in certain areas of the United States during World War I will be avoided.

## MEDICAL EPONYM

### LITTLE'S DISEASE

William John Little (1810-1894) wrote "On the Influence of Abnormal Parturition, Difficult Labours, Premature Birth and Asphyxia Neonatorum on the Mental and Physical Condition of the Child, Especially in Relation to Deformities" in the *Transactions of the Obstetrical Society of London* (3: 293-344, 1862).

Asphyxia neonatorum, through resulting injury to nervous centres, is the cause of the commonest contractions which originate at the moment of birth, namely, more or less general spastic rigidity, and sometimes of paralytic contraction.

The former class of affections may be described as impairment of volition, with tonic rigidity and ultimately structural shortening, in varying degrees, of a few of many of the muscles of the body. Both lower extremities are more or less generally involved. . . . Sometimes the affection of one limb only is observed by the parent, but examination usually shows a smaller degree of affection in the limb supposed to be sound. The contraction in the hips, knees, and ankles, is often considerable. The flexors and adductors of thighs, the flexors of knees, and the gastrocnemii, preponderate. In most cases, after a time, owing to structural shortening of the muscles and of the articular surfaces, the thighs cannot be completely abducted or extended, the knees cannot be straightened, nor can the heels be properly applied to the ground. The upper extremities are sometimes held down by preponderating action of pectorals, teres major and teres minor, and latissimus dorsi; the elbows are semi-flexed, the wrists partially flexed, pronated, and the fingers incapable of perfect voluntary direction.

R. W. B.

## OBITUARY

### LUCIA FLORENCE VICKERY

1860-1941

Dr. Lucia Vickery, a pioneer among women in medicine, died at her home, 37 Greenough Avenue, Jamaica Plain, Massachusetts, on October 23, in her eighty-second year.

Born in Portland, Maine, on April 26, 1860, she received her early education at St. Catherine's Hall at Augusta, Maine. She then studied voice and piano for two years at the New England Conservatory of Music. Deciding to become a nurse, she trained at the Boston City Hospital. After graduating from the hospital, she told the super-

intendent, Dr. Rowe, that she wished to become a physician. When he said, 'Why spoil a good nurse by becoming a poor physician?' she answered, 'I am not going to be a poor physician.'

In 1888, she entered the Woman's Medical College in the New York Infirmary, from which she graduated in May, 1892. In the summer of 1891, she went abroad, visiting hospitals in France and Germany. She interned at the New England Hospital for Women and Children, and then started private practice in Jamaica Plain, in which she was actively engaged for nearly fifty years. In her chosen field of general practice, her contribution was outstanding, and among patients and friends alike, she will be sadly missed. For the past few years, she had maintained a convalescent home, bringing to this later work the same rare success that characterized her general practice. She was a member of the Massachusetts Medical Society, and for several years was elected to the Council.

Among her fellow physicians, her life and work were a constant inspiration. She was strong and kindly in nature, having a forceful personality combined with rare judgment and understanding. Those who knew her intimately found her always cheerful, even in her last illness, with wonderful courage and fortitude. Those who have had the privilege of knowing her well will greatly miss Dr. Vickery.

### SECTION OF OBSTETRICS AND GYNECOLOGY\*

#### FATAL HEMORRHAGE FOLLOWING INTERNAL PODALIC VERSION

A thirty six year old para III had been followed inadequately after the fifth month of pregnancy. She entered the hospital at term and in labor. There was some vaginal bleeding.

Physical examination was negative, and the past medical history was irrelevant. The blood pressure was normal. The uterus was at term. It is stated that hemorrhage during labor, although not severe, was constant. Because labor was ineffectual, the cervix was dilated manually, and an internal podalic version was performed, with the delivery of a stillborn child. There was profuse post partum hemorrhage, from which the patient did not rally. She died while preparations for transfusion were being made.

\*A series of recorded case histories by members of the section will be published weekly. Conventions and lectures by specialists are solicited and will be discussed by members of the section. Lectures should be addressed to Dr. Raymond A. T. U. S. Sec'y, 330 D. M. St., Boston.

**Comment.** From the evidence at hand, there is little to praise in the obstetric treatment given to this patient. Because of a moderate, constant hemorrhage, with ineffectual labor, the cervix was dilated and internal podalic version performed. It is probable that this multipara had a low attached placenta, possibly a marginal previa. In that event, rupture of the membranes, possibly with the insertion of a Voorhees bag, and the use of small doses of pituitary extract would have effected full dilatation of this cervix without further loss of blood, and normal delivery might have followed.

**Accouchement force**, which was probably performed, is an operation of historic interest and has no place whatever in modern obstetrics; it is very likely that the tremendous hemorrhage that followed delivery was caused by rupture of the lower segment of the uterus. Such a procedure cannot be condoned, and is not tolerated in hospitals whose obstetric services are properly supervised. The trustees' responsibility for such disasters has been brought out in this column before they are accountable for good or bad obstetrics and until proper supervision is demanded in all institutions where obstetrics is practised, an occasional case of ill advised operating will result in such a fatality.

### DEATHS

**BLAKE**—ALLEN H. BLAKE, M.D. of Somerville died December 9. He was in his sixty first year.

Born in Cambridge. Dr. Blake received his degree from Harvard Medical School in 1904. He joined the staff of the Somerville Hospital in 1910, and served there until his death. He was a former president of the Somerville Medical Society and of the Middlesex South District Medical Society, and was a member of the Radiological Society of North America. He was a fellow of the Massachusetts Medical Society and the American Medical Association.

He is survived by his widow.

**SAWYER**—WALTER F. SAWYER, M.D. of Fitchburg died December 9. He was in his seventy fourth year.

A native of Keene, New Hampshire. Dr. Sawyer received his degree from Harvard Medical School in 1893. He was a fellow of the American College of Surgeons and a former president of the Worcester North District Medical Society. He was a member of the Massachusetts Medical Society and the American Medical Association.

He is survived by his widow, a son and daughter and four grandchildren.

## NEW HAMPSHIRE MEDICAL SOCIETY

### DEATH

**POTVIN**—VICTOR E. POTVIN, M.D. of Claremont died December 10. He was in his fifty seventh year.

A native of Southbridge, Massachusetts. Dr. Potvin received his degree from the University of Montreal Faculty

of Medicine in 1909. He was a member of the New Hampshire Medical Society and the American Medical Association.

He is survived by his widow, two daughters and three brothers.

## DEFENSE ACTIVITIES

### CIVILIAN DEFENSE

#### DUTIES OF THE LOCAL CHIEF OF EMERGENCY MEDICAL SERVICE

#### Medical Division Memorandum No. 3, Office of Civilian Defense

In order to expedite the organization of the emergency medical services and provide for their effective administration, it is important that each local civilian defense council appoint without delay a local chief of emergency medical service. He should be an outstanding medical leader and should be selected in consultation with the state defense council, the local medical society and the local health officer. To facilitate the integration of all local medical resources into a comprehensive program for civilian protection, the local chief of emergency medical service should be assisted by a medical advisory council, consisting of the local health officer, an experienced hospital executive and representatives of the local medical society, the local nursing profession, the American Red Cross and any participating voluntary agencies.

Under the administrative authority of the local director of civilian defense the duties of the local chief of emergency medical service are:

(1) To determine the scope of the activities of all official and voluntary organizations which are to participate in the emergency medical program of civilian defense, to integrate these organizations into the comprehensive local program and to assist them in expanding their activities to the limit of their resources in personnel and equipment.

(2) To assist hospitals in the locality to organize, equip and train emergency medical field units, as outlined in Medical Division Bulletin No. 1, *Emergency Medical Service for Civilian Defense*.

(3) To inspect and select sites for the establishment of casualty stations.

(4) To make a spot map of the locality, indicating the locations of hospitals, appropriate sites for casualty stations, depots for storage of stretchers, blankets and collapsible cots, and the locations of rescue squads. The map should indicate the number of emergency medical squads in each hospital. Copies of the map should be supplied to control centers, police and fire departments, health department, local Red Cross chapter, state defense council, regional director, regional medical officer and all co-operating hospitals.

(5) To plan and establish adequate transportation service for casualties and medical personnel in consultation with local governmental departments, American Red Cross and voluntary agencies.

(6) To arrange with the local control authority for field drills of emergency medical units and rescue squads in collaboration with police and fire auxiliaries, disaster relief and canteen services of the American Red Cross, ambulance transport service and other civilian defense units, and to supervise such drills.

(7) To make an inventory of hospital beds in the locality and of the possibilities for emergency expansion in bed capacity.

(8) To assist the authorities charged with preparing plans for evacuation in making an inventory of hospitals, convalescent homes, sanatoriums, hotels and other structures within a radius of 50 to 100 miles, which might be used as base hospitals to which patients in city institutions could be evacuated.

(9) To assist the local central volunteer bureau in establishing courses for volunteers in the field of health, medical care, nursing and related activities.

(10) To stimulate recruitment of volunteers for nurses'-aide courses of the American Red Cross, assist the local Red Cross chapter in establishing training centers for volunteer nurses' aides at appropriate hospitals and assist the Red Cross placement bureau in placing nurses' aides with hospitals, clinics, health departments and field nursing services after completion of training.

(11) To stimulate and guide extension of first-aid training courses as widely as possible among the local population through the American Red Cross and other official and voluntary agencies.

(12) To stimulate and guide industrial plants, business establishments and governmental bureaus in the locality in the training and organization of effective first-aid detachments among the employees.

(13) To collaborate with state and local health departments and through them with the regional sanitary engineer in a comprehensive program for the protection of the community against emergency sanitation hazards.

(14) To collaborate with local and state defense councils, Office of Civilian Defense, Federal Security Agency, Children's Bureau and other local, state and federal authorities in the preparation of plans for evacuation, with particular attention to the medical needs of the population under such circumstances.

(15) To keep the community and particularly the members of the health and medical professions and the participating official and voluntary organizations informed of the plans and activities of the local emergency medical service.

## BOOK REVIEW

*That None Should Die.* By Frank G. Slaughter, M.D. 8°, cloth, 423 pp. New York: Doubleday, Doran and Company, Incorporated, 1941. \$2.75.

This is a medical novel written by a physician in active practice. Its action, at least up to a point, is obviously based on personal experience, and the picture of student life and practice, both hospital and private, is reasonable enough. But the author attempts to project just what practice will be under governmental control, of which, with all due respect, neither he nor anyone else can be sure, although each person may have his fears. One is not much interested in stories that take a flier into the future, and as a story pure and simple, — which a conventional novel really ought to be, — this is not a particularly thrilling piece of work.

## THE CARDIOVASCULAR EXAMINATION OF THE ARMY RECRUIT\*

HENRY JACKSON, JR., M.D.†

BOSTON

IT is obvious to anyone who has followed the course of the present war that a high degree of stamina is vital to the modern soldier, perhaps even more so than ever before. It is necessary, therefore, to adhere to the strictest standards when deciding whether or not a man should be classified as "fit for general military service." In reaching a conclusion, one must visualize as nearly as one may from this present distance the rigors of modern warfare, and furthermore, the examiner must bear in mind the question of possible future compensation arising from a certificate of disability discharge.

Criteria that might rightly be applied to civilian life may not be proper for the modern military regime, and it should be constantly remembered that the army of today functions more than ever as a unit and that even the temporary disability of one man may be of grave import to the unit as a whole. Moreover, it is probably incorrect to assume that because a man has been "athletic" in civil life he will necessarily be able to endure the hardships of an extended and concentrated campaign under modern conditions. One professional athlete who had successfully participated in his chosen vocation in October, 1940, was properly rejected by the United States Army for gross physical defects a month later. In this respect, Paragraph 1-b in A. R. (Army Regulations) 40-105 is worth recalling: candidates for commissions in the organized reserves "must be free from any defect or pathological condition which would interfere with the performance of the duty expected of them in the Army, or which would, as a result of service, be especially liable to undergo progressive change or to become the basis for a claim against the Government in the event of call to active service."

This communication is concerned only with the cardiovascular system of the recruit, and much has been learned in this respect in the past twenty-five years. The standards relative to other body systems should be quite as exacting.

Up to May, 1918, "heart disease" ranked third in the list of causes of discharge from the British Army and the Royal Navy,<sup>1</sup> yet in 1938, diseases of the circulatory system accounted for but one tenth of the annual death rate in the United States Army.<sup>1</sup> It is problematical whether this major difference is due to increased attention to the cardiovascular system, to the reduction of the incidence in certain diseases leading to cardiovascular disorders or to the fact that from 1914 to 1918 the British forces were actually at war. It is likely that all these factors are involved. On the other hand, it is interesting that only 0.8 per cent of 37,000 men at Camp Devens up to May, 1918, were rejected for cardiovascular disorders,<sup>2</sup> and that during World War I approximately 0.5 per cent of all men drafted and sent to military camps were rejected for cardiovascular defects.<sup>3</sup> It should be especially noted that neither of these statistical analyses includes those men rejected by their local draft boards. The figures cited correspond more closely to those of the present induction centers (now designated as examining centers). The Metropolitan Life Insurance Company rejects as "ineligible for standard life insurance" approximately 2 per cent of all applicants below the age of thirty-five. Preliminary figures show that, in the past year, slightly over 3 per cent of all men have been rejected for cardiovascular disease by their local examining boards.<sup>4, 5</sup>

The various induction centers of the United States Army are guided in their selection of men by regulations covered in M. R. (Mobilization Regulations) 1-9. At these centers, only men are examined who have been passed as physically fit for general military service by their local selec-

\*From the Thorndike Memorial Laboratory, and the Second and Fourth Medical Services (Harvard), Boston City Hospital, and the Department of Medicine, Harvard Medical School.

†Chief civilian internist, Boston Induction Center, Fourth Recruiting Area; assistant professor of medicine, Harvard Medical School.

tive-service boards, together with those men applying for regular enlistment in the Army and a certain number of aviation cadets who have been, or will be, examined further by a flight surgeon.

Under Paragraph 55 of M. R. 1-9, it is apparent that to be placed without question in Class 1-A (general and unlimited military service) a man must have a cardiovascular apparatus free of all but the most trivial deviations from the strict normal. The apex impulse must be within the midclavicular line, and no thrills or "important murmurs" may be present. The pulse rate must be under 100 and over 50. No cardiac arrhythmias are allowed other than sinus inequality and infrequent extrasystoles. More than transitory hypertension patently due to excitement is disqualifying. Neurocirculatory asthenia, unless mild, is likewise a cause for rejection. All this is as it should be, and it must be especially noted that, at present, the induction centers—in contrast to the local examining boards—either flatly accept or reject a man. The Army does not now consider Class 1-B (limited service), except under very special circumstances requiring a waiver from the War Department. In this respect, the induction centers differ from the local examining and advisory boards, which may, at their discretion, place a man in Class 1-A, 1-B or 4.

However, according to the same regulations, it is incumbent on examining physicians to accept for service men with "accidental functional murmurs" or with other findings that do not indicate disease or impair the selectee's ability to undergo severe bodily exertion, and to exclude those with defects, however innocent, appearing at the time of examination that would interfere with their activities (Paragraph 60, M. R. 1-9).

As a result of the experience of eleven months at the Boston Induction Center, Fourth Recruiting Area, and with the help of several cardiovascular experts, certain conclusions—subject to subsequent change—have been drawn. It seems worth while to bring these conclusions to general attention for future reference and, perhaps, amendment.

~ \* \*

It is obvious that all recruits with organic heart disease of whatever nature should be summarily rejected (Paragraph 57, M. R. 1-9).

No recruit should be accepted if he has a diastolic murmur at either the apex or the base.

It is probably best that all recruits having an undoubted history of rheumatic fever should be rejected, even if there is no demonstrable cardiac damage at the time of examination. The possibility of recurrent rheumatic disease and of late development of valvular or myocardial disease

must be considered. It is obvious that certain men may wittingly and with malice aforethought feign such a history. In such cases, documentary evidence from the patient's physician or hospital records is of the greatest value. On the other hand, men may knowingly conceal their past disease, although there are severe penalties for so doing. In such cases, a history of repeated nosebleeds, continued unexplained fever or chorea (infrequently associated by recruits with rheumatic fever) may be of some help. Recently, a man was accepted by the internist only to be rejected by the neurologist, who elicited an unquestionable past history of chorea of many weeks' duration. In doubtful cases, an electrocardiogram and six-foot film of the heart should be taken before final acceptance or rejection.

All applicants showing arteriosclerosis or arteriolar sclerosis should be rejected.

Any gross inequality of the pulse should be a cause of rejection. It is commonly taught that excitement, sleeplessness, alcoholic excesses and the like predispose to extrasystoles, yet I have been surprised to find how rare this irregularity is in recruits or selectees, even though many of them have been subjected to one or all of the supposed inciting causes. This paradoxical experience should serve to emphasize the importance of any notable arrhythmia.

The question of the significance of systolic murmurs is as difficult at induction centers as in civil life. It seems reasonable that the presence of a low-pitched, soft, systolic murmur localized at the pulmonary-valve area, or even heard at the apex, unaccompanied by other cardiac abnormalities and not preceded by a history of rheumatic fever or chorea, may be regarded as of no consequence, especially if the man appears otherwise healthy and robust. A mitral systolic murmur accompanied by an increased pulmonic second sound, slight cardiac enlargement and a history of rheumatic fever is, on the other hand, obviously a cause for rejection. Between these two extremes lie many cases. There are competent cardiologists who believe that a systolic murmur at the apex, even though loud and transmitted to the axilla, if unaccompanied by other signs should be regarded as consistent with good health. This may well be true in civil life; it is probably not true in war, and there is some evidence that even in civil life such a murmur cannot be dismissed too lightly.<sup>6,7</sup> In this respect, the opinions of Bourne<sup>8</sup> are of interest. Discussing the examinations of the heart in British recruits, this author says: "If a systolic murmur is entirely absent in the erect position, it is unlikely to be organic. If

present only in the erect position, it is almost certainly functional in type. If absent during phases of respiration, it is unlikely to be organic." Essentially the same views are expressed by Parkinson.<sup>1</sup> It is undoubtedly wise to reject any man who shows a loud, harsh, systolic murmur transmitted to the axilla *even though such a murmur is unaccompanied by other pathologic signs*. That this dictum is contrary to the teachings of some is fully recognized. The opinion has not been hastily formed.

Mitral 'presystolic' murmurs are also difficult to appraise. The truly presystolic murmur—especially if of the rough, crescendo type, accompanied by a loud snapping first sound and increased by exercise—should be regarded as a cause for rejection. In many cases, however, a selectee or recruit may come to the induction center with a pronounced tachycardia, and in these men one not infrequently hears what seems to be a presystolic murmur. It is in actuality more a grating quality to the first sound in an overactive heart, and it almost always disappears if the man lies down for half an hour. Such a murmur may be disregarded if no other abnormalities are present and if the past history is negative.

Men with pulse rates of 100 or over should be rejected unless the tachycardia subsides with adequate rest. It is essential to distinguish between the tachycardia caused by an unstable and nervous temperament and that transiently due to excitement, temporary nervousness or lack of sleep. The latter type will almost invariably subside after half an hour's or an hour's recumbency with the added distraction of watching others undergo their examinations. It is obvious that acute infections may similarly be accompanied by tachycardia, usually, the site and nature of the infection can easily be found. Tachycardia that does not subside during the day of examination should probably be regarded as evidence of an unstable cardiovascular or nervous system and should therefore be considered a cause for rejection: a man on active service can scarcely demand a "few days' rest." If the tachycardia is the only abnormality, the examiner may be justified, in rare cases, in asking the man to return on another day for a second examination. Initial rates of 130 or over very seldom come down to normal. Marked tachycardia may follow the use of certain drugs either for therapeutic purposes or because the man being examined is a malingerer. This possibility should always be borne in mind, although not many such cases have been recognized at the Boston Induction Center.

The question of blood pressure is a most difficult one. The regulations (M R 19) state that men should be rejected who have a "persistent blood pressure at rest above 150 millimeters systolic or above 90 diastolic, unless in the opinion of the medical examiner the increased blood pressure is due to psychic reaction and not secondary to renal or other systemic disease." When the first inductions took place in Boston in November, 1940, it was the opinion of one cardiovascular expert that, for all practical purposes, blood-pressure readings could be dispensed with, since the number of true hypertensive patients in this age group would be negligible. This view has gradually been modified, and blood pressures are now taken on all men with initial pulse rates of over 100, on all men showing more than a slightest possible trace of albumin and on all obese applicants. If the blood pressure is more than 150 systolic or 90 diastolic, the recruit is rested until either the pressures have become normal or it is apparent that they will remain elevated during the day of examination. The original practice of having men return on subsequent days for further check-ups has been discarded. If rest for three days is needed to attain normal readings, it is probable that the applicant has either essential high blood pressure or neurocirculatory asthenia. In this area, we have not, so far as we are aware, encountered blood pressures elevated because of drug addiction. In other parts of the country, such falsely elevated blood pressures are not uncommon. The possibility of malingering should always be borne in mind. Adopting a long range and conservative view, and influenced by the work of Hines,<sup>10</sup> we now reject men whose systolic blood pressures remain over 150 and whose diastolic pressures remain over 90 during the day of examination. Grossly elevated blood pressures frequently fall to strictly normal limits within an hour. Such variations from the normal may probably be disregarded.

Neurocirculatory asthenia is, according to Bourne,<sup>11</sup> the "commonest cause of cardiovascular breakdown under the strain of active service." The subjects are usually high strung, repressed, fastidious in their habits and subject to palpitation, precordial distress, abnormal sweating and dyspnea or dizziness on exertion. Occasionally, the dyspnea may be extreme. There is usually an associated tachycardia. The blood pressure, particularly the systolic, tends to be elevated but variable. Sighing and yawning are common stigmas. This condition, which is probably of nervous rather than of cardiac origin, calls for sum-

mary rejection unless it is very mild. It should be noted that the syndrome is rather closely simulated in men who have, the night before examination, been on an alcoholic debauch.

\* \* \*

When all is said and done, it must be admitted that a man is no stronger than his cardiovascular system, and that this system may be subjected

TABLE 1. *Rejections Due to Cardiovascular Abnormalities in 1940 (8708 Men).*

to very severe strain over an indefinitely long period. We are increasingly convinced that the cardiovascular standards for admission to the United States Army should be of the strictest sort. Tables 1 and 2, which are derived from the work sheets of the Boston Induction Center, Fourth Recruiting Area, reflect this increasing conservatism and indicate in a general way the causes of rejection for cardiovascular defects.

It should be noted that the number and percentage of rejections for cardiovascular disease during the second period were materially greater than

TABLE 2. *Rejections Due to Cardiovascular Abnormalities in 1941 (8627 Men).*

## NEW PHYSICAL STANDARDS FOR ARMY PILOTS

CAPTAIN EDWARD T. SPUNT\*

BOSTON

CIVILIAN physicians are aiding the national wartime program greatly through their work in examining selective-service registrants both as voluntary examiners for local selective-service boards and as specialists at Army induction centers. As a result, many physicians are informed about the physical standards required for general military service. There is a different and higher standard, however, for military aviation. With this phase of physical examination for military service, private physicians have had little opportunity to become familiar. This paper describes briefly the requirements for qualification as an airplane pilot in the Army of the United States, as changed December 17, 1941, to meet wartime requirements.

Why should a private physician know something of this? In the first place, there is the medical man's catholic interest in affairs pertaining to his profession. Beyond that, the medical profession has already indicated its zeal in furnishing all possible assistance to the Nation during the present emergency. Such information as this article provides should fit a physician more fully for possible future service of even wider scope.

For those in private practice, there is also a service to be rendered to their patients in this connection. During the month of July, 1941, nearly 1300 New England men between the ages of twenty and twenty-six years, inclusive, applied for examination as Army aviation cadets. Before making official application, many of them went to their own physicians for advice about whether their physical condition warranted the effort and expense of securing an examination from the United States Army. Seldom was the physician in a position to offer advice based on a knowledge of the requirements.

No private doctor is authorized to qualify physically a candidate for the Army Air Corps. Official qualification must be determined by a special Army examining board, which includes a flight surgeon or medical officer and at least another officer. To become a flight surgeon, a medical officer must first take a special course in aviation medicine, during which he observes the effects of flight and high altitudes on physique, as well as on other phases of medicine peculiar to aviation. After successfully completing such

a course, he is authorized to term himself "A.M.E." (aviation medical examiner). If he fulfills his duties in a satisfactory manner as an aviation medical examiner for at least a year, the chief of Army Air Corps may certify him as a flight surgeon.

Even though the private physician cannot qualify a candidate officially, he may be in a position to save his patient from considerable effort and disappointment—that is, he can advise certain patients who may come to him for advice about the possibility of their entering the Air Corps that they definitely will not be able to meet the physical standards. In other cases, the private physician is in a position to encourage ambitious young men to go ahead with their applications as good risks to pass the physical examination. All this would be a service to the Army as well as to the applicant. It would relieve the pressure on the Air Corps examining boards by saving them the fruitless task of examining a large number of applicants who could have been advised earlier that they were not physically suitable.

Of the 1287 men examined during the month of July, 567 were definitely rejected; 589 qualified, and 131 others were tentatively rejected, pending correction of minor defects. Since it takes an average of four hours for the complete examination of one man, the pressure on the Air Corps examining boards is obvious.

Army aviation cadets receive commissions on graduation from the course in flying; their value as future officers must be therefore considered. A number of young men who can qualify physically are not acceptable as aviation cadets because they lack qualities considered vital for a competent officer. Many of these, however, may be eligible for training as sergeant pilots.

Applicants who have had at least two years of college training are exempt from educational examination. Among such college men, the percentage of disqualification has been much smaller than among applicants who lack such training. But young men who have not had college opportunities are also eligible for aviation-cadet training if they pass a written examination in such subjects as algebra, plane geometry, plane trigonometry and English composition. Throughout New England, under the general leadership of the New England Aviation Cadet Committee, these men are being helped to prepare for such examina-

\*Flight Surgeon, First Corps Area.

tions by "refresher courses" given at extremely small fees through state and local departments of education, and through such fraternal and patriotic organizations as the Elks, American Legion and Veterans of Foreign Wars. It is expected that the educational requirements will be revised in the near future to meet the wartime need for manpower.

Candidates for appointment as Army aviation cadets must be male citizens (for at least ten years) of the United States, who at the time of application have reached their twentieth, but who have not reached their twenty-seventh birthday. They may be married only if they sign a statement that their dependents have other means of support. They must be of excellent character and sound physique, and in excellent health. Those who qualify have a splendid opportunity, both in the military service and for later civilian careers in private aviation. As aviation cadets, they are given thirty-five weeks of pilot training, West Point style. During this training, they receive \$75 a month in addition to their food, clothing, lodging, medical and dental care, and a \$10,000 life-insurance policy. On completion of the training, they are appointed second lieutenants, Air Corps Reserve, and are assigned to active duty. While on active duty, they receive an initial lump sum of \$150 to cover expenses for officer's uniform, are paid \$245.50 a month, and receive a cash bonus of \$500 for each year they serve on active duty. Obviously, it is a most desirable appointment.

The following discussion of physical standards is based on Army Regulations 40-105, covering the physical standards and examination procedure for the Form-63 examination of candidates for commissions. These standards are modified for flying duty, particularly those of vision. Their strict observance is considered necessary for the protection of the individual concerned and of those with whom he is associated in Army Aviation.

\* ~ \*

*History.* An intensive examination of the past history of the candidate and of his family is conducted to determine abnormalities that might reveal disqualifying facts. In particular, the patient is questioned to determine the presence of constitutional disease, psychopathic tendencies or previous severe injuries, and evaluation is made regarding possible present or future handicaps as a result of them.

*Eye examination.* This is a most intensive phase of the examination, and more candidates fail to meet the eye standards than any other. Better

vision is obviously necessary for an airplane pilot than for an officer in another branch of the service. The following conditions are disqualifying:

Visual acuity less than 20/20, as tested by the ordinary Snellen chart or self-illuminating test cabinet. The applicant must be able to read the "20 line" of the Snellen chart from 20 feet perfectly, and without difficulty. Candidates with superior acuity are able to read the smallest or "15 line" from 20 feet, and are given a rating of 20/15.

Trachoma, or xerophthalmia; chronic conjunctivitis; pterygium encroaching on the cornea; complete or extensive destruction of the eyelids, disfiguring cicatrices and adhesions of the lids to each other or to the eyeball; inversion or eversion of the eyelids, or lagophthalmos; trichiasis, ptosis, blepharospasm or chronic blepharitis; epiphoria, chronic dacryocystitis or lachrymal fistula; chronic keratitis, ulcers of the cornea, staphyloma or corneal opacities encroaching on the pupillary area and reducing the acuity of vision below the standard noted above; irregularities in the form of the iris, or anterior or posterior synechias sufficient to reduce the visual acuity below the standard; opacities of the lens or its capsule sufficient to reduce the acuity of vision below the standard, or progressive cataract of any degree; extensive coloboma of the choroid or iris, absence of pigment, glaucoma, iritis, or extensive or progressive choroiditis; retinitis, detachment of the retina, neuroretinitis, optic neuritis or atrophy of the optic nerve; loss or disorganization of either eye, or pronounced exophthalmos; pronounced nystagmus, or permanent or well-marked strabismus; diplopia or night blindness; abnormal conditions of the eyes due to diseases of the brain; malignant tumors of the lids or eyeballs; asthenopia accompanying any ocular defect.

Color blindness. Defects of color vision are frequently discovered in men unaware of their presence. Ishihara's or Stilling's test charts are used for the determination of color vision, in addition to the Holmgren wool yarns. Some persons can select the six cardinal colors correctly but have difficulty with the various shades or mixtures. Such men will show color defects when tested with a set of pseudoisochromatic plates (American Optical Company) or the Ishihara plates, and they are disqualified if they miss more than 25 per cent of the plates. A pilot must have normal color vision for many reasons, among others the frequent use of colored lights for night landings and signal operations. There

exists a widespread false belief that color-blind persons are accepted by the Air Corps as observers. This is a myth. The false belief has been traced to a journalist's speculation concerning whether a color-blind observer might not be effective in detecting camouflaged objects because the camouflage was designed for normal eyesight. It is an interesting speculation, but tests have not proved its truth. The value of color blind observers in the field of camouflage detection is questionable, and candidities showing color vision defects are not acceptable for pilot training.

*Ears, nose and throat* Hearing, which is tested by the whispered voice test and the audiometer, when available, must be 20/20 in each ear. On otoscopic examination, there must be no evidence of a serious past inflammatory process that has resulted in sequelae interfering with the auditory or vestibular functions. In the examination of the nose and throat, distinction is made between permanent and temporary disqualifying conditions. For example, marked chronic enlargement of the tonsils or a deviation of the nasal septum sufficient to produce mouth breathing is temporarily disqualifying. After the correction of such temporary defects, a candidate is acceptable, but any irremediable defect or abnormality that materially interferes with the respiratory or olfactory function or with phonation disqualifies permanently. Consideration will show how essential it is for a pilot to have ears, nose and throat in excellent condition, especially when he flies at high altitudes and is thus subject to conditions outside those met in earth bound pursuits.

*Dental examination* Applicants must have a minimum of twelve teeth, which must include three serviceable natural masticating teeth above and three below opposing, and three serviceable natural incisors above and three below opposing. A satisfactory fixed prosthetic appliance may be considered serviceable, provided there is no evidence of infection or degeneration resulting from the pressure caused by the appliance. On the other hand, a removable plate or bridgework is not acceptable as a replacement for natural teeth. Disqualifying dental defects include gross prognathism, gross malocclusion and chronic gum infections, such as marked pyorrhea alveolaris.

*General physical examination* This is similar to the examination prescribed for selective service trainees in Mobilization Regulations 1-9. Care is exercised to detect any abnormalities of the cardiovascular, respiratory, gastrointestinal, endocrine and genitourinary systems. Muscles, bones and joints are carefully examined to determine freedom of motion, muscular co-ordination and evidence of previous disease or injury. The existence

of any form of organic heart disease is disqualifying. A systolic murmur at the apex that is transmitted to the axilla or angle of the scapula disqualifies. A cardiac murmur must be carefully investigated, and electrocardiograms and 6 foot films of the heart taken in an effort to determine whether the murmur is organic or physiologic in origin. Disqualifying is a heart rate of 100 or over, or of 50 or under, when this is proved to be persistent in the recumbent position; or a persistent systolic blood pressure of 140 or over for applicants under twenty five years of age or of 150 or over for those twenty-five years of age or older.

*Height and weight.* To be eligible, a candidate must be between 64 and 78 inches in height. His weight must be between 115 and 217 pounds and must be in proportion to his height. Evidence of obesity, with retarded development of the secondary sex characteristics, or evidence of gynecomastia or cretinism is disqualifying. Cases of underweight are investigated to determine the possibility of constitutional disease, such as tuberculosis, diabetes mellitus or hyperthyroidism.

*Neuropsychiatric examination.* Reflexes, gait, co-ordination and tremors are observed for any disqualifying indications. The function of the cranial nerves is examined, and all abnormalities reported. In addition, the experienced flight surgeon estimates whether the applicant is temperamentally fitted for aviation and appears "adaptable to military aeronautics."

\* \* \*

It is hoped that the foregoing will give civilian physicians a better understanding of the requirements for Army aviation cadets. In addition to helping the physician advise a patient who may be considering entering the Army Air Corps, it may be a helpful guide when young men appear to request help in correcting minor defects so that they may become physically qualified. Common remediable defects include deviation of the nasal septum, hypertrophied tonsils, carious or insufficient teeth, gum infections, overweight and underweight, hernias and varicoceles.

The purpose of these regulations is to conserve life and matériel by selecting for flying duty only men who are physically and mentally fit for such duties. It is, of course, necessary to maintain this standard, and further examinations are therefore made from time to time, with the result that newly developed defects may cause reclassification into lower brackets, either temporarily or permanently.

Equipped with this information, the medical profession should be better able to help their own patients and to serve their country in promoting the slogan—"Keep 'Em Flying."

## ARTERIAL OCCLUSION IN RELATION TO EFFORT\*

## With Special Reference to the Retinal Arteries

HOWARD B. SPRAGUE, M.D.,† AND WALTER WESTINGHOUSE, M.D.‡

BOSTON

**A**MONG the problems of industrial employment of persons with cardiovascular disease, there is none more troublesome than the determination of the relation between vascular obstruction and the work being done at the time of the attack. In coronary occlusion, evidence has failed to prove that a given physical effort can be considered responsible for the closure of the artery, although some studies suggest that subintimal hemorrhage, with or without rupture into the lumen from an atheromatous ulcer, may be precipitated by exertion. This, however, is a matter of speculation, and complete or relative inactivity appears to be the state most commonly present at the time of acute cardiac infarction.<sup>1,2</sup> This observation appears statistically significant even when the usual proportionate time spent by people at rest and while exercising is evaluated.

Although cases of coronary closure during work come most frequently into court for adjudication, there are other types of arterial occlusion in which the relation to exertion becomes a matter of medicolegal interpretation, namely, peripheral embolism and thrombosis, and arterial blocking from spasm or endarteritis. Perhaps the most dramatic is that resulting in sudden loss of eyesight from obstruction to the retinal artery. A case of this sort was the stimulus to the present study.

A sixty-one-year-old man with rheumatic and arteriosclerotic heart disease and aortic stenosis was working as a janitor. He did not complain of cardiac symptoms, and the heart showed normal rhythm except for premature beats. He was tending the fires, and when he opened the furnace door, a slight explosion occurred with a puff of coal gas. He stepped back from the flash and noticed sudden loss of sight in the left eye. He continued to work and carried ash barrels in the afternoon. Following this, he noted tingling in his left arm and foot, and twelve hours later developed paralysis of this side. It was claimed that the effort and excitement of stepping back from the explosion resulted in occlusion of the retinal

artery by an embolus projected from the heart. A review of our experience, which was undertaken in an attempt to discover the probabilities in such a case, was extended to involve a study of other types of arterial occlusion in ambulatory patients in relation to the precise effort that they were undergoing at the time of the attack.

It can easily be seen by a study of hospital records that most emboli, pulmonary and peripheral, occur when the patients are at rest in bed, either postoperatively or suffering from cardiac failure. We are not concerned with this group, since we are interested in discovering what a person, in a presumably ordinary condition of health, may be doing when peripheral embolism or thrombosis occurs.

The patients are divided into two groups: those with and those without eye symptoms. We have 29 patients in the former, with thirty attacks of occlusion, and 46 in the latter, with forty-seven occlusions. Both groups present diagnostic difficulties, particularly patients with retinal-artery occlusion. It is not often necessary to remove such eyes surgically, and the pathologic condition cannot be confirmed by examination. Such occlusion may be due to embolism, thrombosis, endarteritis (at times, syphilitic), prolonged spasm of the artery, as in acute quinine poisoning, aneurysm of the carotid system, cardiac inhibition from painful stimuli, severe hemorrhage, as in bleeding peptic ulcer, or combinations of these factors. In many cases, no obvious general disease is present. It should be understood that we are confining the problem to arterial and not venous occlusion. The latter is about four times as common as arterial obstruction, according to Minton.<sup>3</sup> The retinal picture of arterial blocking is that of ischemia, often with the characteristic cherry-red spot at the macula, and not the gross hemorrhage that is seen in venous obstruction. It seems generally agreed, however, that although embolism of the central artery of the retina remains a popular diagnosis, such embolism is relatively rare, and that obliterating endarteritis with thrombosis is the common cause. According to Kern,<sup>4</sup> no source of embolus can be found in over 66 per cent of the cases. However, cases of bilateral occlusion are *extremely*

rare. In any event, the cardiac conditions that are most commonly associated with intracardiac thrombi should present the best presumptive background for embolism—cardiac infarction, mitral stenosis, auricular fibrillation or subacute bacterial endocarditis. This last condition does not appear in our series, since such patients are very rarely able to work beyond the earliest stages of the disease.

Several studies of the condition have been made, and many individual case reports published, particularly with reference to therapy in those with embolism, such as the use of amyl nitrite, icetyl choline, heparin and massage of the eyeball. We have failed to find any extensive series analyzed with a consideration of the exact activity at the time of the vascular accident. Minton's remarks that such occlusion of the retinal vessels rarely occurs in young people (10 per cent), when it is usually the result of valvular disease of the heart, in over 90 per cent of the cases the lesion appears after fifty years of age, and is due to gradual obliteration of the arteries with final abrupt closure. In his series of 64 cases, activity of the patient at the time of the loss of eyesight is described in only 4: a twenty-three year old woman with mitral stenosis on getting out of bed ten days after a second delivery, a forty-seven year old man with a normal heart on the day following severe hematemesis, a sixty-nine year old man during an attack of influenza, and a forty-eight year old woman who was walking in the street. Minton states, however, that occlusion of the artery may occur at any time of the day, although in most cases it happens in the early hours of the morning. He believes that a slight fall in blood pressure results in a diminished flow to the retinal artery and collapse of a half occluded vessel, with thrombosis and permanent occlusion, but admits that spasm may be a factor.

De Schweinitz and Holloway, in 1908, described 5 cases: a fifty-two year old man with arterio-sclerosis and probable hypertension, who lost his eyesight after many hours of proofreading, a thirty-two year old Negress with an enlarged heart and questionable syphilis, who awoke in the morning with blindness of the left eye, a thirty-two year old woman with mitral stenosis, who lost her vision while giving a massage treatment, a forty-five year old man, who became blind while riding index cards, and a nineteen year old boy with a normal heart, who lost his eyesight while dressing.

Coverdale,<sup>9</sup> in 1929, found 51 cases in the literature and added 11 of his own: a twenty-four year old girl with mitral stenosis, while washing her

hands, became blind in the right eye, a thirty-eight year old woman with mitral stenosis, while riding in a bus, lost the sight of the left eye, a twenty-one year old woman with mitral stenosis and aortic regurgitation awoke with loss of sight in the right eye, a sixteen year old girl with mitral stenosis awoke with blindness of the left eye, a nineteen year old boy with mitral stenosis, while sitting up in the morning, became blind in the right eye, a twenty-one year old woman with a suspicious first heart sound, while making beds, lost the vision of her left eye, a sixteen year old girl with a normal heart became blind in the evening, after swimming in the afternoon, a thirty-six year old man with mitral stenosis and aortic regurgitation, while reading after work, lost the sight of his right eye, a seventy year old man with an enlarged heart, an aortic systolic murmur and a complete heart block, while dressing, slipped but did not fall, and suddenly lost sight in the left eye, a fifty-two year old man with a normal heart, while walking, became blind in the right eye, a sixty-five year old man with an enlarged heart and aortic systolic murmur, while sitting down, noticed that the vision became dim in the left eye—it was better the next day, but he was almost blind the following day.

In these 20 cases from the literature, no loss of vision occurred when the patient was undergoing severe or unusual exertion, 14 cases occurred with mild or moderate effort, and 6 when the patients were at rest.

In 3 of de Schweinitz and Holloway's cases, preliminary symptoms of transient blindness or hazy vision occurred at times prior to the permanent blindness. This suggests in element of spasm or, possibly, transient ischemia from reduced blood flow and, less likely, small emboli before the complete occlusion. Both spasm and emboli small enough to pass into less important retinal vessels have been observed on ophthalmoscopic examination of the retina. Some authors have thought that spasm was precipitated by effort, and that physical exertion should be reduced in patients with a history of transient blindness. In permanent loss of vision from occlusion of retinal vessels, effort appears to play no part. The situation has been compared to angina pectoris, in which unusual effort may precipitate an attack but cardiac infarct from closure of a coronary vessel, or final cumulative ischemia, does not appear to be related to physical exertion. Similarly, it is not unusual for a patient with intermittent claudication from arteriosclerosis of leg vessels to have pain on effort, but to have the final episode, which results in gangrene, appear at rest. In such cases, con-

plete arterial occlusion may not be demonstrable in the amputated specimen.

It might be argued that an increase in the activity of the heart, resulting in increased output and blood velocity, might lead to the dislodgment of mural thrombi and thus result in embolism, and,

Fifteen cases of rheumatic heart disease were studied. The ages ranged from twenty to forty-nine years. There were 12 men and 3 women. One man had two occlusions. Nine patients had auricular fibrillation, 5 had normal rhythm, and 1 had questionable auricular fibrillation. Loss of

\*While lying in bed receiving digitalis, this patient had an attack of blindness in the other eye—six days after an attack of paroxysmal auricular fibrillation.

conversely, that a slowing of the blood stream might more logically be expected to promote thrombosis in the arterial system. The findings in our cases do not support the first part of this hypothesis, if the onset of symptoms can be considered coincident with the vascular blocking.

#### REVIEW OF CASES

##### *Occlusion of Retinal Artery*

The series of cases with occlusion of the retinal artery or its branches included 29 patients, with thirty attacks (Table 1).

sight came suddenly in the right eye in 10 cases, and in the left in 4. In 1 case with aortic stenosis and regurgitation and normal rhythm (Case 2), the right retinal artery was occluded first, and then the left.

It can be said that only 2 of these patients with a total of sixteen occlusions were undergoing unusual physical effort when overtaken by blindness. Six were engaged in mild exercise. Eight occlusions occurred when the patients were at complete rest. It is of interest that the man who had sudden loss of vision in his right eye on blowing his nose while walking (Case 3) was thought

possibly to have had mild typhoid fever some time before but was able to work sacking grain nine and a half hours a day without symptoms.

There were 9 cases of hypertension and arteriosclerosis, 1 of which was complicated by aortic stenosis; only 1 patient had auricular fibrillation. The ages ranged from fifty-five to eighty-one years. Five patients were women. The right eye was involved five times, and the left eye four times. Two patients were doing housework, including sweeping, 1 stepped back from a slight furnace explosion, 1 was bending forward working on an automobile, 2 were dressing, 1 awoke with loss of vision, 1 was at the movies, and 1 noticed loss of vision with a quick turn of his head. Perhaps the man at work on the automobile (Case 20) was engaged in unusual effort. The case of the janitor (Case 23) is questionable. None of the others could reasonably blame their occupations. Endarteritis with thrombotic occlusion seems the best explanation for these cases, with the possible exception of the patient with auricular fibrillation (Case 16), in whom embolism may have occurred.

Two patients were syphilitic: one, a fifty-one-year-old woman (Case 26), also had hypertension; the other (Case 25) was a man of forty-four. Both patients had normal cardiac rhythm. The woman lost the sight of her left eye while ironing, two days after premonitory symptoms lasting ten minutes. The man walked home on a cold day, drank a small glass of whisky and, while walking about the house an hour later, became blind in the right eye. No relation to effort seems apparent in these cases, and endarteritis is the probable cause. Spasm may have been a factor in Case 26.

Three patients in whom no heart or general vascular disease was found were as follows: a twenty-eight-year-old woman who went blind in the left eye while she was walking, a thirty-five-year-old man who lost vision in the left eye while sitting listening to the radio, and a thirty-three-year-old woman who became blind in the right eye while she was asleep. Blood serologic findings were negative for syphilis in all 3 cases. Two patients in this group were at rest, and 1 was engaging in mild effort.

These 30 cases of occlusion of the central artery of the retina, or its branches, occurred in 29 patients. Three patients were engaged in rather strenuous physical effort and, 15 in mild to moderate effort, and 12 were at rest.

#### *Nonretinal Arterial Occlusion*

In a series of 46 cases, with forty-seven attacks, the occlusion was not in the vessels of the eye (Table 2).

Twenty-two patients with rheumatic heart disease—14 women and 8 men—were included. The ages ranged from twenty-six to sixty years. Four patients had normal rhythm, and 18 had auricular fibrillation; 3 had multiple occlusions. Of the whole series, 9 patients had occlusions of the cerebral vessel, 12 had occlusions in the arteries supplying the legs, and 5 had occlusions in the arms. In this group, it is likely that the occlusions were due to emboli from auricular thrombi arising from the combination of mitral stenosis and auricular fibrillation.

In no case did the embolism occur during violent effort. In 2 cases, it happened some time after unusual effort: in one (Case 43), fifteen minutes after running for a trolley, and in the other (Case 47), after the patient had fixed a bed. In 9 cases, embolism occurred during mild effort, such as rising in the morning, driving a car and eating breakfast. In this group, 2 patients (Cases 37 and 44) were somewhat more strenuous, one playing golf, and the other working as a baker. In 11 patients, or half this group, embolism occurred while the patients were at complete rest.

Twenty-three patients with arteriosclerosis or hypertension, or both,—15 women and 8 men,—who had sudden vascular occlusions were studied. The ages ranged from forty-five to eighty-two years. One other patient, a man of forty, without demonstrable cardiovascular disease (Case 75), was also observed. He had a sudden embolus to the left posterior tibial artery, with recovery following embolectomy. The sites of the occlusion in twenty-five occlusions in 24 patients were as follows: brain, 3; legs, 19; arms, 2; and abdomen (superior mesenteric artery), 1. Auricular fibrillation was present in 10 patients (possible paroxysmal auricular fibrillation in 2), premature beats in 2, complete heart block in 1, and normal rhythm in 11. In no case was the patient engaged in severe or unusual effort, and 12 patients were at complete rest.

#### DISCUSSION

It is essential to determine the relation between arterial occlusion caused by embolism, thrombosis, endarteritis or vascular spasm, and the physical effort engaged in by the patient at the time of the episode or for an indefinite interval preceding it. This relation may determine not only the responsibility of the effort for the occlusion, but also the wisdom of insisting on inactivity for victims of cardiovascular disease.

In the series here presented, embolism appears to be the likeliest mechanism for occlusion in the 38 cases in which auricular fibrillation was pres-

 †Patient later had an occlusion of the left arm.

ent, as well as in the 37 cases of rheumatic heart disease with or without auricular fibrillation—in 10 nonretinal cases, operation or autopsy proved this to be so. Local vascular disease, with or without spasm, was the probable cause in the other cases.

Some observers have recently suggested the transfer of the blame for sudden coronary occlusion into a rather remote past, claiming that events and activities in the life of the patient, days or even weeks prior to the occlusion, could be held responsible. Such a view opens the way to tremendous legal complications. Certainly, arterial embolism cannot be included in such a hypothesis, and this study concerns only the immediate precipitating factor. The question is, Does the effort in which the patient is engaging just prior to, or during, the occurrence of embolism have anything to do with washing off intracardiac material and releasing it into the blood stream? On a priori grounds, it seems that strenuous effort might do just this.

However, in our 38 patients with auricular fibrillation, in whom speeding of the blood stream by effort might conceivably be such an excitant of embolism, the occlusion occurred only twice a few minutes after severe effort, sixteen times with mild to moderate effort, and twenty times at rest. It may be objected that cardiac patients with auricular fibrillation, or older arteriosclerotic persons, cannot engage in violent effort to prove or disprove this assumption. Our figures suggest,

however, that there is no reason to suspect that the ordinary activities of the patients' lives are likely to precipitate embolism; that unusual effort is not an expected cause of arterial occlusion; and that the mechanisms of arterial blockage are as progressive when the patient is at rest as when he is active, and perhaps more so.

In this group of seventy-seven occlusions, sudden loss of eyesight, or of the use of a limb, or occlusion of cerebral or mesenteric vessels, based on embolism or other arterial blockage, occurred during ordinary daytime activities, or when the patients were at rest, in over 9 out of 10 cases.

#### SUMMARY AND CONCLUSIONS

Seventy seven attacks of acute arterial occlusion in 75 ambulatory patients are described. 30 of these occurred in the retinal arteries of 29 patients, and 47 occurred in other peripheral arteries of 46 patients.

In 3 cases, the occlusion took place during rather severe effort, and in 2, a few minutes after unusual exertion; in 37, the occlusion occurred coincident with mild or very moderate effort, and in 35, when the patient was at rest in bed or sitting in a chair.

Peripheral arterial occlusion from embolism, thrombosis or endarteritis rarely occurs during unusual physical effort even in patients with cardiovascular disease of a degree compatible with quite strenuous exertion. In our series, such occlusion occurred approximately fourteen times as

commonly when the patient was at complete rest or when engaged in the ordinary exertions of his usual life.

In approximately half the entire series of arterial occlusion,—embolic and obliterative,—the patient was physically inactive. This suggests that the conditions necessary for either embolism or thrombosis are as effective with reduced as with increased blood flow, and that the occurrence of such an accident is at least fortuitous.

## TUBERCULIN TESTS IN CHILDREN

### An Interpretation of a Series of Varying Intradermal Test Doses and of a Comparable Series of Patch Tests

CLEMENT A. SMITH, M.D.,\* WILLIAM H. FAULKNER, M.D.,† AND JOSEPH M. CORDI, M.D.‡

BOSTON

IT has been the usual custom to perform the intradermal or Mantoux tuberculin test in the Out-Patient Department of the Children's Hospital by injecting 0.1 cc. of old tuberculin diluted 1:1000. As a result of this dilution, an actual dose of 0.1 mg. of tuberculin comes in contact with the intracutaneous tissues. Although a weaker initial dose is occasionally used for patients suspected of strong tuberculin allergy, experience in this clinic has not led to apprehension that more than 0.1 mg. is too great an amount for routine testing. On the other hand, some doubts have arisen that it may not be strong enough to give dependable diagnostic evidence. Since patients are frequently brought to the clinic from a considerable distance and since their transportation usually involves at least one other person, it is highly desirable that repeated visits for retesting be avoided unless there is reason to believe that a negative response to the 0.1-mg. dose is unreliable.

Although most authorities advise that patients negative to 0.1 mg. be retested with 1.0 mg. (0.1 cc. of 1:100 dilution) of tuberculin, the percentage who react only to the larger dose is variably stated. Thus, Hart,<sup>1</sup> in the London investigation of 1929, found that 96.3 per cent of patients with known tuberculosis reacted to 0.1 mg., and that this percentage was raised to 97.3 by retesting the negative patients with 1.0 mg. In a series of controls from the general population, he found that 40.5 per cent reacted with 0.1 mg., whereas the percentage increased to 43.5 with the stronger dose. Lincoln,

Raia and Gilbert<sup>2</sup> have recently presented evidence to show that in New York City a much larger percentage of children negative to 0.1 mg. may react to increased doses. These authors found that 17 (10.9 per cent) of 155 such children reacted to 1.0 mg. The most striking data have come from the Lymanhurst studies. Harrington, Myers and Levine<sup>3</sup> published in 1937 their statistics on the sensitivity to tuberculin of over 4500 children and adolescents from five to eighteen years of age. Of this number, 8.7 per cent were positive to 0.1 mg. of tuberculin, but another 9.2 per cent of the total group were positive to 1.0 mg., although they failed to react to 0.1 mg. Thus, not even half the tuberculin-sensitive patients would have been discovered had the testing not been carried beyond the usual 0.1-mg. injection. In another context, Myers<sup>4</sup> cautions that "the administration of a sufficient dosage of tuberculin is important as a 10 to 20 per cent error may result from using only the small dose." Unfortunately, various series of data are not presented in a manner facilitating direct comparisons, but the experience with adults at the Boston City Hospital may be mentioned. Of 100 patients reacting to 1.0 mg. of tuberculin, 81 were found to react to 0.1, 48 to 0.01, and 14 to 0.001 mg. This indicates that an error of about 20 per cent would result from depending on 0.1 mg. as the test dose.

Such statements as these raise doubt concerning the validity of a clinic procedure in which all children negative to a routine strength of tuberculin are not called back for a stronger test. Therefore, a primary reason for the present study was to determine the error, if any, that might be avoided by performing these second tests on every infant and child not reacting to 0.1 mg.

A second problem for consideration was the degree of reaction to which positive significance could be ascribed. This became significant particularly because of frequent errors in interpretation of tests read for us by visiting nurses and, in some cases, by health officers and family physicians. The error was almost always that of interpreting the faint redness of a dubious or negative test as positive, a mistaken impression later rectified by retesting with stronger solutions but only after considerable parental confusion, if not distress, had been brought about. In an attempt to avoid such difficulties and still to spare crowding of the clinic and unnecessary transportation of children, we now ask parents of patients living at a distance to measure the diameters of redness and of swelling at the injection site and to send us these objective data on a mimeographed postal card. Proper interpretation of such objective data requires as definite standards as possible. It should be mentioned in passing that indefinite reactions are not limited to outpatients but occasionally confuse the diagnostic data of ward patients as well, and that reference to the directions for interpreting tuberculin reactions as given in *Diagnostic Standards*\* does not always evaluate the dubious induration or the inconstant edema.

#### EXPERIMENTAL PROCEDURE

A quantitative testing procedure was devised to answer the two questions, What strength of tuberculin is sufficient to elicit a positive reaction? and What local manifestations constitute such a reaction? When a child in the hospital was discovered to react to the routine test with 0.1 mg. of tuberculin, and was not deemed an unfavorable subject because of fever, serious illness or other cause, he was retested on the other arm with simultaneous injections of 0.1, 0.01 and 0.001 mg. of tuberculin, respectively, or 0.1 cc. of 1:1000, 1:10,000, and 1:100,000 dilutions. The preparation used has been standard for many years in this hospital, and consists of O.T. (old tuberculin) supplied by the Saranac Laboratories and made up to the proper strength with carbolyzed saline solution. Fresh dilutions are made once a month and kept in refrigerators when not in use. In some patients whose original reactions to 0.1 mg. were very slight, the graded tests consisted of 1.0, 0.1 and 0.01 mg. In all cases, the sites of injection were spaced sufficiently far apart so that resultant erythemas would not coalesce, and the strongest solution was injected proximally so that lymphatic drainage could not carry more tuberculin into sites where smaller

amounts had been injected. These simultaneous graded tests were read at twenty-four, forty-eight, seventy-two and ninety-six hours thereafter, by outlining the extent of erythema and of induration on tracing paper placed over the reactions. So relatively scarce have tuberculin-positive children become in our wards that it was necessary to turn to another source to augment our series of such patients. At the North Reading State Sanatorium, through the courtesy and interest of Drs. Earle Willoughby and Gerald Caron, we were enabled to test 75 children in various stages of tuberculous disease and healing. In that institution, testing is not ordinarily made with doses stronger than 0.01 mg., and there seemed little reason for changing the procedure during this series of investigations, since children positive to 0.01 mg. would, of course, have reacted to 0.1-mg. tests also, and should give questionable reactions at the sites of still weaker doses. Accordingly, most of the North Reading children were tested only with 0.01 and 0.001 mg. of tuberculin. Some received 0.0001 mg. as well, but in every case simultaneous doses of at least two strengths were applied.

The combined groups from the Children's Hospital and the North Reading State Sanatorium furnished a total of 118 tuberculin-positive children who were tested in this general manner. In addition to these, another unselected group of about twice their number who did not react to tuberculin in the standard 0.1-mg. dose in our wards were tested with graded doses in the same way. In these, the tests usually consisted of doses of 0.1, 1.0 and 10.0 mg. Thus, 336 tuberculin-positive and tuberculin-negative children were injected with at least two and usually three simultaneous test doses (Table 1). From the results, it was possible to determine the number failing to react to 0.1 mg. but positive to 1.0 or to 10.0 mg. It was also hoped—and to some extent this hope was realized—that the responses would give some clue of what might be called a positive reaction, since weak or questionable reactions should be noted in children whose definitely positive responses to stronger amounts gave proof of their tuberculin sensitivity, just as there would also be doubtful responses in others proved by stronger tests to be tuberculin negative. Thus, a study of both types of borderline reactions might lead to criteria concerning the time of appearance and fading, degree of induration and so forth, which would guide our future interpretation of isolated questionable reactions.

This study also gave an excellent opportunity to compare the sensitivity of the Vollmer tuberculin patch test with the response of children to

\*In *Diagnostic Standards*, published in 1940 by the National Tuberculosis Association, edema is considered an essential of a positive reaction; edema of more than 5 and less than 10 mm. diameter is required for a + reaction.

various strengths of O.T. administered by the Mantoux technic. Accordingly, at the time graded tests were applied to one arm, the patch test\* was applied on the other arm, or more commonly on the upper back. The patches were removed after forty-eight hours, and read then and at seventy-two and ninety-six hours by the same tracing-paper technic. Thus, the study was made to answer a third question, What is the relative sensitivity of the Vollmer test as compared with the Mantoux test in various dilutions?

RESULTS

Adequate Tuberculin Dosage

The positive reactors from Table 1 have been listed in Table 2 with the percentage of children

If 70, instead of 7, per cent of our patients reacted to tuberculin, the group requiring more than 0.1 mg. would be larger but only proportionately so, and the percentage should therefore not change. An unquestionable testimony to the comparative accuracy of the 0.1-mg. dose appears when the results are contrasted with those using 0.01 mg. It will be noted from Table 2 that 84 per cent of those reacting to 0.1 reacted to 0.01 mg., whereas only about 40 per cent of the latter group were positive to 0.001 mg. Such great discrepancies appear between graded tests weaker than 0.1 mg., and so little increase in accuracy results from tests stronger than 0.1 mg. that we shall continue to consider it a satisfactory single-strength test for routine clinic purposes. It should be mentioned,

TABLE 1. Reactions to Simultaneous Tests in 119 Tuberculin-Positive and 217 Tuberculin-Negative Children Grouped according to Presumable Susceptibility.

GROUP	PRESUMABLE SUSCEPTIBILITY OF GROUP	No. OF CASES	REACTION •	AMOUNT OF O. T. IN TEST DOSE				
				10.0 MG.	1.0 MG.	0.1 MG.	0.01 MG.	0.001 MG.

reacting to any one dose expressed in terms of their response to a dose ten times as strong. Of 118 children who reacted to 1.0 mg., 97 per cent were found to react to 0.1 mg. Thus, in the Boston vicinity and in children younger than twelve years, the 0.1-mg. dose of tuberculin should bring to light all but 3 per cent of the positive reactors. Obviously, this will not apply everywhere, and it can be stated here only with qualifications. One reason for the practical accuracy of the test is the small number of tuberculin-sensitive persons in the clinic community, since the smaller that number is, the less frequently will one encounter the occasional state of mild allergy. A comparison of the amount of tuberculosis observed among our patients with that observed at older age levels and in different places cannot be included here. It may be stated, however, that in the last statistics available from children tested in the Out-Patient Clinic (with 0.1 mg. O.T.) the findings were: 0.7 per cent positive reactions among 190 infants under three years; 1.8 per cent among 315 children from three to five years; 2.7 per cent among 325 children from six to eight years; and 7.0 per cent among 220 children from nine to eleven years.

\*The test material was kindly furnished by the Lederle Laboratories, Incorporated, Pearl River, New York.

however, that in individual diagnostic problems in which the degree of allergy may be masked by

\*Not tested with this dose but reacted to weaker dose.

fever, intercurrent infections or very early or very far-advanced tuberculosis, adaptation of the dose to the patient may be necessary. The increasing

use of P.P.D. (purified protein derivative) necessitates some expression of the results mentioned above in terms of that preparation, but only a rough comparison is possible on the basis that 0.01 mg. of O.T. is about equivalent to the first-strength dose of P.P.D., and that 1.0 mg. O.T. may not elicit quite so many positive reactions as the second-strength dose.<sup>3</sup> We have not adopted P.P.D. as a routine tuberculin because of its expense and because the first-strength dose is too weak and the second-strength too strong for a routine single test; nevertheless, in occasional diagnostic difficulties requiring extreme accuracy of testing, the second-strength dose is a valuable check on strong doses of O.T.

#### True and False Positive Reactions

The 336 patients in this study were tested with a total of nearly a thousand individual Mantoux tests (Table 1). Of this total, the interpretations of a certain number were, as was anticipated, questionable, and thus would have been, as isolated tests, dubious in significance. Their characteristics are given below. Since the results from simultaneous stronger and weaker tests were available, it was hoped that some observations might be made by which these doubtful responses could be interpreted.

There were two main groups of questionable reactions: those in children whose simultaneous stronger tests proved them to be definite reactors; and those in children whose other tests, histories and physical findings gave no evidence to suggest tuberculin sensitivity. The first group might be called "weak positive reactions," and the second "false positive reactions" or "pseudo-reactions."

*Weak positive tests* showed an erythema 1 cm. or less in diameter, with extremely indefinite induration. Such responses, although they may fall in the + group according to *Diagnostic Standards*, and thus were listed as positives in Table 1, have occasionally been misleading and are always interpreted with hesitancy. An analysis of their characteristics as shown in this study is given in Table 3. It will be noted that an almost equal number of these weak responses was called forth by 0.001 and by 0.01 mg. of tuberculin, but their behavior was somewhat different when classified according to the dosage. Weak responses to 0.001 mg. showed a tendency to increase in area or to remain of the same size between the twenty-four hour and forty-eight-hour readings. Fading during this period was less common, so that two thirds still showed an area of erythema at least 2 mm. in diameter even after seventy-two hours. On

the other hand, similar weak responses to 0.01 mg. showed less tendency to increase in area or to hold their size with the passage of time, and a smaller number persisted to three days. It appears that the weaker the test dose used, the more

TABLE 3. *Number and Behavior of Weak Reactions in Children Definitely Positive to Stronger Doses.*

DOSAGE AND TYPE OF REACTION	No. OF TESTS
Weak reactions to 0.001 mg. O. T.	33
Increased or remained of same intensity from twenty four to forty eight hours	22
Faded in intensity from twenty four to forty eight hours	11
Some reaction still perceptible at seventy two hours	22
Weak reactions to 0.01 mg. O. T.	31
Increased or remained of same intensity from twenty four to forty eight hours	14
Faded in intensity from twenty four to forty eight hours	17
Some reaction still perceptible at seventy two hours	17
Weak reactions to 0.1 mg. O. T.	2

significant is a faint type of reaction, particularly if it does not diminish in intensity after the first twenty-four hours. In fact, this series of tests shows that any response of from 5 to 10 mm. in diameter at forty-eight hours might be interpreted as positive, provided it was called forth by a dose of 0.01 mg. or, better still, by one of 0.001 mg.

It is striking that with tests of 0.1 mg., although nearly three hundred were applied and a fifth were positive, only two weak reactions occurred. In one of these children, although a definite response was obtained with 1.0 mg., the 0.1-mg. test produced only 7 mm. of erythema (no induration) at forty-eight hours and complete fading by seventy-two. In the other, the 0.1-mg. reaction reached a height of 6 mm. of erythema and 2 mm. of induration at forty-eight hours, with an impalpable 3-mm. stain at seventy-two hours.

It is difficult to speak with complete certainty of *false positive reactions* or *pseudoreactions*, since by definition they must occur in tuberculin-negative children, and the presence of any sort of response to tuberculin makes one hesitate to call a person negative. However, these reactions differed sufficiently from the weak positives just described to make us believe that they had no positive significance. It will be seen in Table 4 that they were encountered most frequently with the stronger doses, only one occurring at the site of 0.1-mg. injections and none with any weaker dose. These reactions were characterized by rapid fading; thirty subsided entirely within forty-eight hours, although many were erythematous areas 3 cm. or even more in diameter at twenty-four hours, and a few were somewhat swollen though not defi-

nately indurated. One reaction persisted until forty-eight hours, and one did not appear before the forty-eight-hour reading. Both of these subsided completely in another twenty-four hours, leaving no sign except the needle mark. Heise and Brown<sup>6</sup> describe reactions to glycerin broth used in preparing tuberculin; this may be the mech-

TABLE 4. *Pseudoreactions in Tuberculin-Negative Children.*

anism of some of these phenomena, since their occurrence increases with the amount of O.T. used.

It appears that whereas doses smaller than 0.1 mg. may not bring out tuberculin sensitivity or may elicit weak and rather insignificant reactions in positive children, doses stronger than 0.1 mg. call forth an increasing number of rapidly fading pseudoreactions. These possibilities must be borne in mind in interpreting responses to very strong or very weak solutions. Although no absolute rules of interpretation can be made from these observations, they suggest that the presence of even 2 mm. of erythema and induration at seventy-two hours indicates tuberculin sensitivity, especially if the dose employed was 0.01 mg. or less. In other words, the smaller the dose, the more attention is to be paid to faint but persistent reactions; and the larger the dose, the more a dubious reaction is likely to be of no significance, particularly if it begins to fade after the first day. Practically all the unquestionably positive reactions were marked by 1 or 2 cm. of erythema and induration and reached their maximum at forty-eight hours. At that time, the erythema was at its height, and although the induration sometimes became somewhat firmer at seventy-two hours, it was rarely any more extensive in area than before. This observation bears out the figures given by Stewart<sup>7</sup> regarding the growth in area of tuberculin reactions. No reactions beginning to appear later than forty-eight hours were encountered in this study, although a child has been observed in this hospital whose positive response to 0.1 mg. of tuberculin did not appear until the fourth day.

The present study indicates the advantages of the 0.1-mg. test dose, but its potential disadvantages must be considered. Lincoln and Grethmann<sup>8</sup> have recently called attention to the distinctly undesirable activation of disease in and around existing tuberculous foci that may result

from the diagnostic injection of tuberculin. They cite 7 cases in which there was reason to believe that this had occurred. In 2 of these, the dose of tuberculin injected was 0.01, in 1 it was 0.06, in 3 it was 0.1, and in 1 several doses given within twenty-four hours made a total of 0.26 mg. Thus, dangers may be associated with comparatively small, as well as large, doses. No immediate exacerbation of pulmonary or other lesions has been observed to follow tuberculin testing in past years in this clinic, although the usual dose has been 0.1 mg. Nevertheless, a regard for the possibility of such an occurrence has often led to the substitution of weaker doses when strong allergy is suspected, and in the present investigation the proper range for simultaneous tests was established only after the relative sensitivity of the patients had been indicated approximately by previous single tests. However, the patch test was applied to all patients, some of whom (as noted below) responded with marked manifestations at its site, so that many children had simultaneous reactions to that test, as well as to two and occasionally three of the intradermal inoculations. There were no evidences of unfavorable activation around tuberculous foci. Thus, although agreeing that caution is necessary in the use of tuberculin, we believe that experience allows the recommendation of 0.1 mg. of old tuberculin as a routine dose for the Mantoux test on young patients such as those in this clinic. The use of smaller amounts is suggested for patients suspected of skeletal or lymph-node tuberculosis, pleural effusion, phlyctenular keratitis and erythema nodosum, for those with a history of long exposure to the disease, and for persons above twelve years of age. In passing, it may be mentioned that the degree of tuberculin sensitivity to the graded and measured tests in this investigation showed no relation to the extent or seriousness of the tuberculous process.

The Patch Test

Vollmer and Goldberger,<sup>9</sup> in 1937, introduced the application to the skin of filter-paper squares soaked with pure O.T. as a test of tuberculin sensitivity. The case of this technic, for both physician and patient, aroused immediate interest, and the relative accuracy of the method has been indicated by several published studies recently summarized by Vollmer.<sup>10</sup> With one outstanding exception, the agreement between the patch and the Mantoux reactions has been quite close.

In the study here reported, 336 infants and children were tested with simultaneous patch and Mantoux tests. As shown in Table 5, no patient who failed to react to the Mantoux test gave any

reaction to the patch, so that the latter test cannot be suspected of producing false positive results, nor did it bring to light positive reactors not discovered by intradermal testing. In 113 children, there were positive reactions to both tests; among this group were several cases in which the weaker intradermal doses brought forth no response. Of the 6 patients in whom the two tests disagreed, 3 reacted only to comparatively strong intradermal doses. Thus, in this study, patients responded to the patch tests in nearly the same degree as to the 0.1 mg. intradermal doses. Apparently, except in rare cases, the patch makes a suitable screening test and would be highly efficient if followed, when negative, by a strong intradermal inoculation, such as the introduction of 10 mg. of OT.

As others have observed, an occasional unpleasantly large and uncomfortable reaction to the patch test was noted, and here again the mani-

TABLE 5 Comparison of Patch and Intradermal Tests

RESULT OF PATCH TEST	RESULT OF INTRADERMAL TEST	NO. OF CASES
Negative	Negative (all doses)	217
Positive	Positive (any dose)	113
Negative	Positive (0.1 mg.)	3
Negative	Positive (1.0 mg.)	2
Negative	Positive (10.0 mg.)	1

festations at the sites of the patch and intradermal tests ran roughly parallel. Although the actual patches of filter paper impregnated with tuberculin are only 1 square cm. in area, each of these occasionally called forth an induration of 3 cm. or more in diameter, with vesiculation and, at times, shallow ulceration. Since two such squares are present on each strip of adhesive (on either side of a control square of plain filter paper), the reactions may coalesce into a large single area. Besides these situations, it was noted that the children often spoke of itching at the patch-test sites, although there was seldom any complaint from the intradermal reactions. Vollmer<sup>10</sup> has pointed out the possibility of avoiding severe reactions by using weaker tuberculin solutions in the manufacture of the patches or, more simply, by leaving them in contact with the skin a shorter time.\*

\*We have made a few observations using transparent Scotch cellulose tape instead of adhesive and suggest it as a satisfactory backing for the test patches. The immediate surroundings of the impregnated filter paper squares can be kept under observation at the earliest sign of redness seen through the transparent tape, the whole strip can be removed. This is suggested as a means of avoiding unnecessarily prolonged application of tuberculin to the skin of very sensitive subjects.

## SUMMARY AND CONCLUSIONS

Simultaneous intradermal (Mantoux) tests with graded doses of O.T. (old tuberculin) were performed on 336 infants and children under thirteen years of age. The same patients were also tested by the patch method.

Test doses of less than 0.1 mg. were less than 85 per cent as accurate as those of 0.1 mg. in revealing tuberculin sensitivity. Doses of 0.1 mg. were 97 per cent as accurate as those above that amount.

Weak positive or questionable reactions in patients with actual tuberculin allergy were usually noted in weak test doses. These reactions were characterized by a tendency to persist as mild manifestations at the site of inoculation for three or four days.

False positive reactions or pseudoreactions in patients seemingly without tuberculin allergy were the results of strong doses and may have been brought about by sensitivity to the broth. These were characterized by widespread erythema at twenty-four hours but almost complete disappearance at forty-eight.

Since the minimum number of doubtful responses was obtained with 0.1 mg. of OT, and since this dose is only slightly, if at all, more liable to induce undesirable perifocal reactions than weaker tests are, it seems to be the most suitable amount for a routine intradermal test of clinic children in the vicinity of Boston.

The tuberculin patch test was positive in 113 (97 per cent) of 116 children who reacted to 0.1 mg. or less of O.T. by the intradermal method.

No correlation between tuberculin sensitivity and degree of infection was apparent.

## MEDICAL PROGRESS

### THE ENCEPHALITIDES OF VIRUS ETIOLOGY\*

JOHN H. DINGLE, M.D.†

BOSTON

THE largest epidemic of encephalitis of known etiology that has hitherto been reported occurred during the past summer and fall.<sup>1</sup> Approximately 3000 persons were affected in an area encompassing the north central states and Canadian provinces. This outbreak, however, did not appear without forewarning. During the last ten years, similar but less extensive outbreaks have occurred in the Midwest,<sup>2-8</sup> as well as in the East<sup>9, 10</sup> and Far West.<sup>11-18</sup> The most recent epidemic appears now to be merely a higher peak in a series of recurrent waves. The clinical aspects of the disease during these outbreaks have been very similar, but have also been distinctly different from those associated with the older type of encephalitis, which appeared in 1916 and has been variously termed "epidemic encephalitis," "encephalitis lethargica" and "von Economo's disease,"<sup>19</sup> and the etiology of which is unknown. In the recent outbreaks, three distinct etiologic agents, all viruses, have been demonstrated. Newer developments in laboratory technic have now made it possible to identify them, to trace their distribution, and to relate them to a given outbreak. These subjects will be discussed in this report, together with a brief review of the clinical manifestations of these diseases and their treatment and prevention.

#### ETIOLOGY, OCCURRENCE AND DISTRIBUTION

Much confusion has existed in the past, and still exists, regarding the diagnosis of encephalitis. Thus, Wilson,<sup>20</sup> in a chapter on epidemic encephalitis, discusses encephalitis lethargica, Japanese B encephalitis and St. Louis encephalitis, with the implication that they are but variants of the same basic disease. Literally, the word encephalitis means "inflammation of the brain." It has been used loosely to characterize a number of clinical

syndromes, — in themselves not too definite, — regardless of etiology. These clinical pictures may be produced by a variety of agents: bacteria, parasites, toxins, chemicals, viruses and, presumably, others as yet unknown. Difficulty in diagnosis and classification is almost certain to exist until the etiology of the various types of encephalitis is determined, and until the clinical criteria for diagnosis are carefully re-evaluated in the light of the etiology. Similar confusion has existed with other morbid states: pneumonia, for example, may be produced by oils (lipoid pneumonia), gases, dusts, a variety of bacteria and viruses.

During the last fifteen years, the discovery of a number of viruses affecting the central nervous system has helped to clarify the problem of encephalitis, and has permitted more or less detailed, although tentative, classifications on an etiologic basis.<sup>21-28</sup> For practical clinical purposes, the encephalitides of man may be divided into three groups:

- Group I. Bacteria, protozoa and other parasites
- Group II. Viruses
  - St. Louis encephalitis
  - Equine encephalomyelitis (Eastern and Western types)
  - Japanese B encephalitis
  - Australian X disease
  - "Forest-spring" encephalitis of Russia
  - Lymphocytic choriomeningitis
  - Louping ill
  - Virus B
  - Poliomyelitis
  - Rabies
- Group III. Etiology unknown, possibly virus
  - Encephalitis lethargica (von Economo's disease)

A number of other conditions are sometimes included in classifications of encephalitis, namely, postinfection encephalitis, postvaccinal encephalitis, postrabic-treatment encephalitis, the large group of primary demyelinating diseases and a miscellaneous group of degenerative processes caused by chemicals, toxins and so forth. No useful function would be served by including these encephalopathies in the above classification, although they must be kept in mind in differential diagnosis.

\*All articles in this series will be published in book form: the current volume is *Medical Progress: Annual, 1940* (Springfield, Illinois: Charles C Thomas Company, 1941. \$4.00).

Of these three subdivisions, only those due to specific viruses (Group II) are concerned here. Since poliomyelitis and rabies constitute special and rather well defined problems,<sup>29-30</sup> they will not be considered further.

Only two types of virus encephalitis, other than poliomyelitis, have thus far occurred in significant epidemics in this country. These are St. Louis encephalitis and equine encephalomyelitis. Other forms have occurred either sporadically, such as rabies and lymphocytic choriomeningitis, or as a result of laboratory infections, such as louping-ill and virus B. Japanese B encephalitis, Australian X disease and 'forest spring' encephalitis of Russia have been epidemic in their respective countries, but have not been seen and recognized in the Western Hemisphere.

### *St. Louis Encephalitis*

In the late summer of 1932, 38 cases of an unusual type of encephalitis occurred in Paris, Illinois.<sup>31</sup> No etiologic diagnosis was made. The following summer, however, more than 1000 cases of a similar disease occurred during August, September and October in and about St. Louis and Kansas City.<sup>32-34</sup> Cases of some kind of encephalitis, possibly the same disease, had existed in this area prior to the 1933 outbreak, since in the St. Louis Children's Hospital sporadic encephalitis had shown a seasonal distribution, with a peak in July and August, during the previous fourteen year period. In any event, a virus pathogenic for monkeys and mice was isolated in 1933 from several fatal cases<sup>31-34</sup> and was shown by almost all investigators<sup>32-39</sup> to be a new different and specific agent. This was the first outbreak of acute encephalitis in this country in which a virus was definitely established as the etiologic agent.<sup>40</sup>

It was found that serums from patients who had recovered from the disease contained substances that would specifically neutralize or prevent the development of infection in animals otherwise susceptible to the St. Louis virus.<sup>32</sup> This test therefore provided a method of determining what persons had been infected with the virus, either acutely or subclinically as well as the geographic distribution of the disease. Thus, in the St. Louis area it was found that serums of about 90 per cent of the convalescents and about one fifth of the 'normal controls' who had not been ill contained neutralizing substances, whereas such antibodies were not found in the serums of patients with typical encephalitis lethargica (von Economo's disease), poliomyelitis and postinfectious encephalitis.<sup>41-44</sup> Furthermore, serologic evidence indicated that the virus was not confined to the St. Louis area but had presumably caused the

outbreak in Paris, Illinois, as well as sporadic cases in New York City and the central and western states. Since 1933, repeated outbreaks have occurred in the Midwest and Far West, with apparently increasing frequency and size, and widening geographic distribution.<sup>7-11, 15, 17, 18, 44-47</sup> A significant factor in this process may have been the migration of labor populations from the Dust Bowl to the Far West.<sup>48</sup> During the last three years, cases apparently due to the virus of either St. Louis encephalitis or the Western type of equine encephalomyelitis, or both, have occurred in the same outbreaks.<sup>6-10, 15, 17, 18</sup> With the exception of the 2 patients in New York City, no proved cases of St. Louis encephalitis have been reported from the Atlantic Seaboard.

### *Equine Encephalomyelitis*

Until 1938, equine encephalomyelitis was considered to be primarily a disease of horses. Although the infection had probably existed on this continent for a number of years, it was first identified as a distinct entity by the isolation of the virus from horses during the 1930 epizootic in the San Joaquin Valley in California.<sup>49</sup> During 1931 the disease was recognized in horses throughout California, in Oregon and in Nevada.<sup>50</sup> In 1933, another virus was isolated from horses in the eastern section of the United States.<sup>1, 5</sup> These two strains of virus were found to be immunologically distinct and to differ from other known viruses.<sup>6, 51-53</sup> They have since been known as the Western and Eastern strains of the virus or equine encephalomyelitis. By the end of 1937, the disease was reported in all sections of the United States except New England,<sup>54-60</sup> and a similar disease was reported from Mexico.<sup>61</sup> In 1938, extensive outbreaks occurred in thirty-nine of the forty-eight states, including New England,<sup>62</sup> and a third, distinct strain of virus was identified in Venezuela.<sup>64</sup> Since then, the disease has occurred in horses throughout the country.<sup>65</sup> Curiously enough, the western and eastern varieties of the virus have shown until recently a sharp geographic delimitation in distribution, the Appalachian Mountains providing the boundary. Both types have now been isolated in Alabama, however, and the Eastern strain has been found in Texas.<sup>66</sup>

The history of the recognition and apparent spread of human encephalitis due to the viruses of equine encephalomyelitis is similar to that of the disease in horses. In 1931, in California Meyer<sup>67</sup> encountered 3 human cases with pathologic lesions similar to those found in horses, although the virus was not isolated and neutralizing antibodies were not demonstrated. During the next six years,

there was no record of outbreaks in man, although the viruses were widespread, as indicated by the occurrence of the disease in horses. There was some suggestion that sporadic cases occurred during this period.<sup>65, 69</sup> In the summers of 1937 and 1938, however, outbreaks of encephalitis occurred in California, North Dakota, Minnesota, Saskatchewan and Massachusetts, and an etiologic diagnosis was established by the isolation of both types of the equine virus and demonstration of specific neutralizing substances in the serums of patients.<sup>5-8, 12, 48, 70-75</sup> The epidemic in Massachusetts was due to the Eastern variety of virus; all the others were due to the Western type. One strain of the Eastern virus isolated from a fatal human case produced typical encephalomyelitis in the horse.<sup>76</sup>

During the last three summers, no epidemics have occurred in the East, but outbreaks of increasing severity have been reported in the Midwest and Far West,<sup>15, 17, 18</sup> culminating in the extensive outbreak during the past summer in the north central states and the adjoining provinces of Canada.<sup>1</sup> As pointed out above, both the Western equine and St. Louis viruses have been isolated in California, Colorado, North Dakota and Washington.<sup>7, 14, 15, 17, 18, 68, 77</sup> Thus far, the evidence indicates that the recent epidemic in the Dakotas and surrounding states and in Canada is due to the Western strain of equine virus,<sup>78-80</sup> although poliomyelitis probably coexists in certain areas. Sporadic subclinical and fatal infections have been reported in laboratory workers.<sup>81-83</sup>

#### *Other Types of Encephalitis*

Three other specific types of acute encephalitis have occurred in epidemic form, namely, Japanese B encephalitis, Australian X disease and the "forest-spring" encephalitis of Russia.

The Japanese disease has been recognized since 1871.<sup>84, 85</sup> It is caused by a specific virus,<sup>35, 38, 86, 87</sup> which is apparently related antigenically to, although not identical with, the St. Louis virus.<sup>38, 88-90</sup>

Australian X disease, or the so-called "mysterious disease," occurred in New South Wales in 1917 and 1918 and returned in milder form in 1922 and 1926.<sup>91-94</sup> It has not been seen since. Enough evidence was obtained, however, to show that the infectious agent was probably a virus, although the strain has been lost so that comparison with the other viruses in this group has been impossible.

Recent reports<sup>95-98</sup> have described a seasonal encephalitis that has existed in Russia for at least twenty-five years. It occurs in the spring, attacks

primarily men laboring in the forest, and accordingly is known as "forest-spring" encephalitis. The etiologic agent is a virus that is distinct from that of St. Louis encephalitis but is antigenically related to the virus of Japanese B encephalitis. Differentiation is possible, however, by immunologic methods.

The virus of louping ill, under natural conditions, produces an encephalitis of sheep in Scotland, where no epidemics or even sporadic cases in man have been reported, although accidental laboratory infections have occurred.<sup>99</sup> The disease is of chief interest academically because of the similarity of the experimental infection to that produced by other viruses causing acute encephalitis.

The B virus was isolated from the central nervous system and spleen of a laboratory worker who had developed an acute ascending myelitis following the bite of a monkey.<sup>100, 101</sup> Apart from such accidental infection, this disease is unknown in man.

Lymphocytic choriomeningitis, a natural disease of mice, occurs sporadically in man.<sup>102-105</sup> The specific virus has been isolated from patients. The disease appears to be primarily a meningitis, but because of the lack of pathological data, the extent of involvement of the central nervous system in man is unknown.

#### TRANSMISSION AND HOST RESERVOIRS

The source and manner of spread of the viruses causing encephalitis in man presented a puzzling problem that has tested the ingenuity and imagination of a large number of investigators. Even in the earliest outbreaks, it became evident that individual contact did not explain the occurrence and spread of the infections. Certain aspects of the epidemics—seasonal occurrence, geographic distribution and related outbreaks in animals—suggested animal and avian host reservoirs and vector transmission. During the last few years, this concept has been substantiated to a considerable degree. In fact, for only two of the known virus encephalitides—poliomyelitis and Australian X disease—is evidence of potential animal reservoirs lacking, and vector transmission is possible with at least five of the viruses.

This advance has been achieved by the correlation of several types of data obtained by studying the following: the epidemiology; the susceptibility of domestic and wild animals and birds; the distribution of the virus in blood and tissues of experimentally or naturally infected animals and birds; the isolation of the virus from naturally infected animals and birds; the presence of neutralizing substances in the blood of

man and of wild and domestic animals and birds; the experimental transmission by vectors; and the isolation of the virus from naturally infected vectors and the transmission of disease by them to normal susceptible animals.

### *St. Louis Encephalitis*

Studies of the 1933 outbreak in St. Louis did not reveal the mode of transmission,<sup>3, 4</sup> although, on reanalyzing the data, Casey and Broun<sup>100</sup> came to the conclusion that every known feature was common to that of a mosquito-borne disease. Although the virus was found only in the central nervous system of fatal cases,<sup>31</sup> it has been demonstrated in the blood of experimental animals.<sup>107</sup> Infection could be produced by intranasal inoculation, as well as by direct intracerebral injection.<sup>32</sup> Clinical signs of infection occurred in monkeys and mice, and possibly in mules,<sup>4</sup> but the other common laboratory animals were resistant. The virus was not found in mosquitoes collected in epidemic areas.<sup>3</sup> One species of anopheline mosquito became infected by biting a diseased animal,<sup>108</sup> but transmission was not accomplished.

Additional information then followed rapidly. The fact that mice could apparently be immunized by intranasal instillation of nasopharyngeal washings from patients<sup>109</sup> suggested that subinfective amounts of virus were present in the nasal secretions and that contact infection might therefore be possible. Wild mice were found to be susceptible,<sup>110</sup> and adult mice contracted the disease by eating infected, newly-born mice, suggesting a possible mode of transmission in nature.<sup>111</sup> The common mosquito, *Culex pipiens*, was able to take up the virus but not to transmit it.<sup>112</sup> Certain individual field and meadow mice were found to be susceptible to the St. Louis virus, whereas others were resistant<sup>113</sup>; this suggested that the latter had acquired immunity from natural infection or were carriers and hence potential reservoirs of the virus.

Because the serums of a significant number of wild and domestic animals and birds were found to be capable of neutralizing the St. Louis virus,<sup>17, 18, 114</sup> the possibility of previous infection was indicated. Inoculation of St. Louis virus intracerebrally into horses whose serums contained neutralizing antibodies resulted in no apparent illness, whereas animals whose serums did not contain antibodies developed an acute encephalitis, indistinguishable from that produced by the virus of equine encephalomyelitis.<sup>115</sup> During the course of this experimental disease, the infective agent was found in the nasal secretions but could not be detected in the blood. It seems unlikely, therefore, that transmission from the horse could be

accomplished by blood-sucking insects. Since the virus is present in nasal secretions, transmission by contact or by mechanical vectors may be possible, with the nasopharynx as the portal of entry.

Finally, Hammon and his co-workers<sup>110</sup> reported the isolation of St. Louis virus from mosquitoes (*C. tarsalis*) collected from areas in which human encephalitis occurred. This insect may therefore be the vector, and several species of wild and domestic birds and mammals may be the host reservoirs; both horses and human beings may be only accidental victims. It remains to be determined, however, whether the virus is actually present in the blood of these animals and birds, whether it can be transmitted from them to susceptible hosts by mosquitoes, and whether or not contact produces infection. Until such data are available, the epidemiology of this disease will remain incomplete.

### *Equine Encephalomyelitis*

Soon after the recognition of epidemics of equine encephalitis in horses, it was noted that the disease disappeared in the fall shortly after the first frost, which suggested the possibility that an insect vector might be involved. This suspicion was strengthened by Kelser's demonstration,<sup>117</sup> amply confirmed by others,<sup>118-124</sup> of the experimental transmission of the disease in the laboratory by mosquitoes. Studies of both the Western and Eastern strains of virus by many investigators<sup>125-142</sup> revealed the wide range of infectivity of the agents for animals and birds by several routes of infection. Furthermore, the virus could be detected in their bloods in the early stages of the disease.

On the basis of the epidemiology of the disease in horses in the eastern United States, TenBroeck, Hurst and Traub<sup>143</sup> considered birds as possible host reservoirs. This hypothesis was supported during the 1938 epidemic in the East by the isolation of the virus from the ring-necked pheasant<sup>144, 145</sup> and the pigeon,<sup>146</sup> and recently in the West from the prairie chicken.<sup>78</sup> Mosquitoes capable of transmitting the infection existed in these areas,<sup>1, 124, 147</sup> but numerous attempts to isolate the virus from mosquitoes collected during epidemic periods failed. More recently, however, neutralizing antibodies for the Western strain of equine virus were found in the serums of a number of wild and domestic birds and mammals in epidemic areas in the West,<sup>144</sup> and the virus was isolated from mosquitoes (*C. tarsalis*) collected in these areas.<sup>110</sup> Thus, it seems probable that mosquitoes are important vectors in transmitting equine encephalomyelitis among birds and ani-

mals, the primary hosts, as well as to man, a secondary host.

Outbreaks have been recorded, however, in an area that had been dry for months and absolutely free from mosquitoes for weeks before the appearance of the disease.<sup>8</sup> It is entirely possible that arthropod vectors, such as the tick, may be involved.<sup>148, 149</sup> Moreover, the Western strain of equine virus has recently been isolated from naturally infected *Triatoma sanguisuga*, commonly known as the assassin bug or the bloodsucking cone nose, and in one case the disease has been transmitted to guinea pigs<sup>150</sup> by this arthropod.

### Other Types of Encephalitis

Considerable information is available regarding the host reservoirs and mode of transmission of certain other encephalitides of virus etiology. Japanese B encephalitis can be transmitted by mosquitoes (*C. pipiens*), but host reservoirs are not known, although monkeys, mice and sheep are susceptible to the virus.<sup>38, 85, 86, 88, 90, 151, 152</sup> The virus of the "forest-spring" encephalitis of Russia has been isolated from rodents in endemic areas and can be transmitted by ticks.<sup>95-98</sup> Little is known regarding Australian X disease except that the monkey, sheep, horse, calf and possibly guinea pig were shown to be susceptible. Louping ill is primarily a disease of sheep and is transmitted by the sheep tick, *Ixodes ricinus*.<sup>153</sup> No vectors are known for virus B encephalitis, which presumably is a disease of monkeys.<sup>100, 101</sup> Lymphocytic choriomeningitis is a natural disease of mice, but the virus has also been isolated from guinea pigs, monkeys and dogs, as well as from man,<sup>154</sup> and laboratory transmission has been effected by mosquitoes.<sup>155</sup>

### CLINICAL AND PATHOLOGICAL ASPECTS AND DIAGNOSIS

The acute encephalitides of virus etiology that occur epidemically are remarkably similar in their clinical aspects, so that in the present state of knowledge differentiation between them on this basis is not possible, except in cases of poliomyelitis.

St. Louis encephalitis<sup>4, 18, 47, 156-158</sup> and the Eastern<sup>9, 70, 73, 74</sup> and Western<sup>1, 5, 7, 14, 15, 18, 68, 77, 82, 83, 159</sup> types of equine encephalomyelitis have occurred epidemically in man in this country. Each of these diseases has appeared in midsummer or late summer. The onset of illness was usually abrupt, although in some patients a prodromal period occurred, characterized by a grippe-like syndrome of fever, malaise, muscle pains and so forth. Headache, fever, mental confusion and

signs of meningeal irritation were outstanding features. In severe cases, drowsiness, tremors, convulsions and coma occurred early in the course, particularly in the younger age group. Jaundice was apparent in some cases.<sup>18</sup> Signs of involvement of the central nervous system varied considerably. Some showed only hyperactive reflexes, whereas others developed extensive paralyses which were usually spastic. Ocular manifestations were rare. The acute illness usually subsided in one or two weeks, and the majority of deaths occurred within the first week. Sequelae were rare in patients who recovered from St. Louis encephalitis,<sup>157</sup> but were frequent and often severe in those—particularly children—surviving equine encephalomyelitis.<sup>68, 74, 77</sup> The mortality was much higher with the Eastern type of equine encephalomyelitis than with either the Western or St. Louis type, which is in keeping with the greater virulence of the Eastern strain of equine virus.

Examination of the cerebrospinal fluid revealed elevated protein, normal sugar and a pleocytosis varying from 10 to 2000 cells per cubic millimeter. In general, the cell counts were lower, 50 to 250, and mononuclear cells predominated with St. Louis encephalitis, whereas the total counts were higher and polymorphonuclear cells predominated in the early stages with equine encephalomyelitis. Polymorphonuclear leukocytosis was found in the blood of some patients.

The pathologic changes in each of these varieties of encephalitis were localized chiefly in the central nervous system and were essentially similar.<sup>7, 73, 71, 160-162</sup> Edema, congestion, cellular infiltration about vessels and in the parenchyma, neuronal degeneration and neuronophagia were present. The process was diffuse, although the spinal cord was usually spared. Considerable parenchymal infiltration with polymorphonuclear leukocytes, arteritis and thrombosis of small arteries and arterioles were found in the brain and brain stem of fatal cases due to the Eastern strain of equine virus.<sup>162</sup>

Differential diagnosis is often difficult,<sup>163</sup> particularly in sporadic cases,<sup>164</sup> and a final etiologic diagnosis must be made with laboratory aid (Table 1). The Western strain of equine virus has been found in the blood<sup>8, 75</sup> and cerebrospinal fluid<sup>82</sup> early in the course of this disease. Each of the viruses has been isolated from the nervous tissue of fatal cases.<sup>70-72, 78</sup> Animals are usually employed for this purpose, although tissue culture may be a more sensitive method.<sup>165</sup> An etiologic diagnosis may also be made by the demonstration of neutralizing or complement-fixing antibodies in serums<sup>27, 79, 80, 166, 167</sup> or cerebrospinal fluid from

convalescents<sup>107</sup> Neutralizing antibodies may be detected by the end of the first week after onset in some cases,<sup>26 107</sup> but more frequently during the second and third weeks. The most reliable evidence is obtained when serums taken during the acute and convalescent stages show an increase in titer.

As mentioned earlier, encephalitis lethargica or von Economo's disease was a fairly definite clinical syndrome, which differed in many respects from the acute encephalitides just described. Following its appearance in 1916, the disease increased

progressed for years, with remissions and relapses. The pathologic changes were inflammatory in nature and most prominent in the area of the basal ganglia. The presence of varying stages of inflammation and nerve cell degeneration suggested persistence of an active process late in the course of the disease.<sup>108 109</sup> The etiology was not established, in spite of extensive investigation, and it is therefore not possible to classify this syndrome as a virus disease.

Lymphocytic choriomeningitis is characterized chiefly by the signs and symptoms of meningeal

TABLE 1 *Certain Differential Features of the Encephalitides Occurring in Man in the United States*

TYPE OF ENCEPHALITIS	SEASON	AGE	ONSET	COURSE	SEQUELAS	APPROXIMATE MORTALITY %	CEREBROSPINAL FLUID		PRESENCE OF SPECIFIC VIRUS		CENTRAL NERVOUS SYSTEM	PRESENCE OF CIRCULATING ANTIBODIES
							WHITE CELL COUNT	PREDOMINATING CELLS	BLOOD	CEREBROSPINAL FLUID		
St. Louis	Late summer	Adults	Sudden	Acute	Rare	20	10-1000	Mononuclear	?	?	+	+
Eastern equine	Late summer	Children	Sudden	Acute	Frequent and severe	0	70-7000	Polymorphonuclear early mononuclear late	?	?	+	+
Western equine	Late summer	Any	Sudden	Acute	Frequent and severe	20	100-1000	Polymorphonuclear early mononuclear late	+	+	+	+
Encephalitis lethargica	Winter	Any	Sudden gradual or not apparent	Chronic	Frequent and progressive	30	0-100	Mononuclear	0	0	0	0
Lymphocytic choriomeningitis	Any	Any	Sudden	Acute	Very rare	0	100-5000	Lymphocytes	+	+	?	+

to epidemic proportions, reaching a peak in 1924 and 1925 and declining during the next few years. New cases have been comparatively rare during the last decade. This form of the disease occurred in the winter and affected all age groups. The onset of acute symptoms and signs was sudden in some cases, gradual in others, and at times was unrecognized until the appearance of sequelae. Low grade fever, minimal evidences of meningeal irritation, headache and, occasionally, somnolence were the chief early manifestations. The cerebrospinal fluid showed minimal changes—slight increase in protein and a count of 10 to 50 mononuclear cells—or none at all. The illness was ordinarily chronic and gradually progressive. Ocular paralysis, somnolence or drowsiness, emotional changes and, sometimes, paralysis occurred during the succeeding weeks and months. Emotional and mental deterioration and Parkinson's syndrome were usually characteristic features. In some cases, complete recovery occurred, in others, the disease

irritation, although drowsiness and coma may occur. Other conditions that must be considered in differential diagnosis are acute meningitis, chronic meningitis (tuberculous and syphilitic), the post-infection encephalitides and other demyelinating processes.

### TREATMENT

Treatment of all the encephalitides is chiefly symptomatic at present. Lumbar puncture and the intravenous administration of hypertonic dextrose solutions are of value in relieving increased intracranial pressure. Sedation and correction of dehydration should be carried out when indicated. Chemotherapy with sulfonamides is of no value, except for the prevention or treatment of complications, such as bronchopneumonia.

Specific antiserum has been employed in horses and experimental animals, with conflicting results.<sup>110 112</sup> Convalescent human serum was of no demonstrable therapeutic value during the St.

Louis epidemic.<sup>173</sup> As Hammon<sup>18</sup> has pointed out, specific therapeutic antisera are of no avail at the present time because a sufficiently early etiologic diagnosis cannot be made. Rosenow and his co-workers<sup>4, 174</sup> have reported studies indicating that streptococci are etiologic agents of the various types of encephalitis. On the basis of this work, they have advocated antistreptococcus serum and streptococcal vaccines for therapy and prophylaxis. Their results have not been confirmed by other investigators.<sup>4</sup>

### PREVENTION

Three methods of attack now appear to be applicable to the prevention of epidemics of encephalitis in this country: extermination of host reservoirs, extermination of vectors and immunization of susceptible hosts. The evidence now available indicates that the natural reservoirs may be so widely diverse in animals and birds<sup>78, 111, 141-146</sup> as to make their extinction impossible. Measures to control mosquitoes and other insects are feasible in many populated areas of the country, and should be carried out where applicable. Immunity to equine encephalomyelitis can be produced in susceptible hosts by vaccines containing the specific virus, which has been killed by formalin or ultraviolet light.<sup>175-179</sup> Such vaccines have been used in horses, with apparently good results.<sup>63, 65, 179</sup> Purified vaccine<sup>180-182</sup> is now available and has been employed in human beings with only minor reactions.<sup>183, 184</sup> Its use seems to be desirable in laboratory workers and in those persons in endemic areas whose occupations offer frequent opportunity for infection. Animals have been immunized against St. Louis encephalitis virus by the use of living virus,<sup>185, 186</sup> but vaccines that can safely be used in man are not yet available.

Further investigation of the problems of prevention is essential, because of the military activities and concentration of men in training camps situated in endemic areas.

CASE RECORDS OF THE  
MASSACHUSETTS GENERAL HOSPITALANTE MORTEM AND POST MORTEM RECORDS AS USED  
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C CABOT

TRACY B. MALLORY, M.D., Editor

## CASE 27521

## PRESENTATION OF CASE

*First admission.* A thirty-year old Italian housewife was admitted to the hospital because of swelling of the legs and abdomen for three weeks.

About six years before entry, the patient had a slight sore throat, followed shortly by painful swelling of her joints. She remained in bed for three months, because a local physician thought "her heart was affected." Her tonsils were removed, and she remained well until four years before entry when again she had "rheumatism," and stayed in bed for two or three months. At this time, some abscessed teeth were found and removed. Following this illness, there was insidious onset of shortness of breath. Dependent edema appeared about eight months before entry, and was not relieved by theocin, which was given by the patient's physician.

Her past and family histories were not of importance. She had an eight-year old son.

On examination, the patient appeared well developed but poorly nourished; she was markedly dyspneic, with cold extremities and circumoral cyanosis. The neck veins were distended. The heart was enlarged 4 cm to the right and 12 cm. to the left of the midline, and fibrillated at a rate of about 156, only about half the beats coming through at the wrist. There was a prominent precordial heave, and a diffuse systolic murmur at the apex, with a mid diastolic murmur and thrill. Each lung field exhibited basal rales. The liver border was tender, and lay three finger breadths below the costal margin. Free fluid was present in the lower abdomen, and the sacral tissues and lower extremities were quite edematous.

The temperature was 97°F, the pulse 92, and the respirations 25.

Examination of the blood showed a red cell count of 6,010,000 with 90 per cent hemoglobin, and a white-cell count of 7400 with 62 per cent polymorphonuclears. The blood Hinton reaction was negative. The urine showed a slight trace of albumin, and contained many hyaline casts and a few white blood cells per high-power field. An electrocardiogram confirmed the diagnosis of

auricular fibrillation, and demonstrated prominent right-axis deviation, with inversion of T waves in Leads 2 and 3. The vital capacity was 1200 cc. The basal metabolic rate was -16 per cent.

The patient was given diuretics and Southey tubes, with improvement in her condition. In the fourth hospital week, total thyroidectomy was performed. Tetany developed after the operation, the blood calcium falling to 8 mg., and the blood phosphorus rising to 6 mg. per 100 cc. Following recovery, the patient was discharged at the end of the second hospital month on digitalis and calcium chloride. By this time, the basal metabolic rate had fallen to -21 per cent, the vital capacity had improved to 1450 cc., and the pulse had become regular at 70.

*Second admission* (one year later). The patient was readmitted because of pain in the back and because of recurrence of her dyspnea and edema. She had remained in bed on digitalis. Nine hours before reentry, she experienced a sudden, sharp pain in her left flank and soon afterward passed a small amount of bloody urine. She was found to be in congestive failure, the condition being little changed from that observed on the first entry, except for the presence of hematuria, which persisted throughout the two weeks of her hospital stay, and except for slight evidence of hypothyroidism—dry skin, a basal metabolic rate of -27 per cent, a blood pressure of 110 systolic, 93 diastolic, and a pulse of 60. The nonprotein nitrogen was 47 mg. per 100 cc. Three and a half liters of dark yellow ascitic fluid was removed by tap. The patient was given Salyrgan and discharged improved.

*Third admission* (four months later). The patient was readmitted with her usual complaints of dyspnea and edema, to be discharged two weeks later after the usual diuresis. The heart rhythm was regular, and the urine was normal except for the presence of albumin.

*Fourth admission* (three and a half years later). During the preceding four years, the patient had been able to do light housework, remaining fairly well until two and a half months before readmission. She then had a cold, accompanied by pain in the chest and migratory swelling of the fingers, shoulders and knees. After a week, the dyspnea, orthopnea and edema reappeared. Re-examination showed a rumbling apical diastolic murmur in addition to the old systolic murmur. The heart was again in fibrillation, and the blood pressure had risen to 115 systolic, 70 diastolic. The white cell count ranged from 13,000 to 15,000, with 76 per cent polymorphonuclears. The sedimentation rate was elevated to 15. The blood

calcium was 9.8 mg., and the blood phosphorus 5.3 mg. per 100 cc. The urine showed a ++++ test for albumin and contained many white blood cells, with a few casts and red blood cells per high-power field. On discharge, after two months of bed rest, there were persistent signs of active disease in the joints.

*Fifth admission* (six months later). The patient returned to the hospital because of a return of congestive failure. She was discharged improved, after a month.

*Sixth admission* (four months later). The patient was once more admitted because of decompensation. The basal metabolic rate had risen to normal. The calcium and phosphorus levels of the blood were each 7.1 mg. per 100 cc. She was given AT-10 (the calcinosis factor of previtamin D), and elevation of the blood-calcium level to 12 mg. per 100 cc. was attained. A colon-bacillus infection of the urine was discovered and treated satisfactorily with mandelic acid.

*Seventh admission* (two weeks later). The patient received the usual treatment for recurrent decompensation, to be discharged after a month.

*Eighth admission* (fifteen months later). The patient was hospitalized for a day because of "numbness" in the hands and face, and a "tight feeling" in the abdomen. The Chvostek and Trousseau signs were markedly positive, and she appeared to be in incipient tetany. The symptoms were relieved by an increase in the daily ration of calcium lactate.

*Final admission* (one month later — seven and a half years after her initial entry). The patient was readmitted because of progressive dyspnea. She had been leading a bed-chair existence. Two days before entry, she began to have considerable pain in the abdomen.

On examination, she appeared acutely ill, severely dyspneic and orthopneic, and quite cyanotic. The heart was enormous, beating irregularly in slow, coupled rhythm. Murmurs were present as before. Rales extended half way to the angle of the scapula on the right. The liver was several centimeters below the level of the umbilicus and was acutely tender. There was little peripheral edema.

The temperature was 99°F., the pulse 40, and the respirations 18. The blood pressure was 120 systolic, 70 diastolic.

Examination of the blood showed an elevation of the white-cell count to 15,400. The blood calcium was 8 mg., and the phosphorus 14 mg. per 100 cc. Other laboratory studies were much as before.

The temperature rose to 101.2°F., and the pulse to 100. Death occurred suddenly and unexpectedly on the third hospital day.

#### DIFFERENTIAL DIAGNOSIS

DR. RICHARD J. CLARK: This patient was quite evidently one of that group subjected to total thyroidectomy for the treatment of heart failure a few years ago. Six years before the first admission, she had acute rheumatic fever, with cardiac involvement aggravated by a second bout of infection two years later, when she first showed symptoms of congestive heart failure that progressed up to her entry into the hospital. At entry, she was in acute congestive failure, with cardiac enlargement and auricular fibrillation. She showed evidence of mitral damage, with an apical systolic and mid-diastolic murmur and thrill. The electrocardiogram at entry was consistent with mitral disease and right ventricular hypertrophy. The temperature and white-cell count afforded no evidence of active rheumatic infection at this time. The findings in the urine were consistent with those of congestive heart failure.

The patient's condition improved with diuretics and Southey tubes. Although the basal metabolic rate was -16 per cent, a total thyroidectomy was performed. This must have been one of the early cases in the series, because later it was believed that the presence of an initially low basal metabolic rate gives a relatively poorer outlook for improvement with this type of therapy. The patient developed clinical and laboratory evidence of hypoparathyroidism after the operation, but otherwise made a good convalescence. I note that four weeks after total thyroidectomy the basal metabolic rate had fallen only to -21 per cent, which is not much of a drop from the preoperative rate of -16.

One year later, the patient re-entered the hospital with recurring congestive failure and also pain in the left flank followed by bloody urine. Evidently she had experienced what is not uncommon in the disease complex — a renal infarct. The nonprotein nitrogen and the diastolic blood pressure were elevated. This gives strong evidence of frank renal disease. The basal metabolic rate was only -27 per cent. Apparently, no thyroid medication was given. If a total thyroidectomy was actually performed, a rate considerably lower than this would have been expected at this time.

The third admission, four months later, gives us little added data. The patient was still in failure. Her rhythm at the moment was regular.

On the fourth admission, she reported an improved state. For four years, she had been able

to do light housework, up to the evident development of recurrent active rheumatic fever following a respiratory infection. The mitral stenosis was apparently becoming more marked, with a rumbling mitral diastolic murmur. Laboratory studies confirmed the presence of active infection. The urine showed many white cells in addition to albumin, casts and blood cells. In spite of this, the blood pressure was relatively low.

Six months later, the patient re-entered the hospital with congestive failure.

On the sixth admission, four months later, she was again in failure. Surprisingly, there was a normal metabolic rate. There is still no mention of thyroid medication. This strongly suggests that the supposedly totally ablated thyroid gland had regenerated, but she still had hypoparathyroidism. She showed a definite colon-bacillus infection of the urine.

The seventh admission was for further congestive failure. The eighth admission was for treatment of incipient tetany.

The final entry (seven and a half years after the initial entry) was for further congestive failure. The patient had considerable abdominal pain, just where we are not told, but there is little to correlate this with, except for the enlarged, tender liver. She had a rise in temperature and white-cell count. There is no positive evidence on which to say whether this was recurrent rheumatic infection or terminal pulmonary infection, or even urinary infection. The heart had become "enormous." Slow irregular rhythm with coupling indicates a diseased myocardium, if not made toxic with digitalis. We have no details regarding the sudden and unexpected death. A massive pulmonary embolus may have occurred, but there is no positive evidence for this. The patient may very well have had acute cardiac dilatation and standstill, with acute pulmonary edema.

There can be little doubt that this patient had primarily rheumatic heart disease, with chronically recurrent rheumatic fever. She must have developed an extreme degree of mitral stenosis. There was never any evidence of aortic involvement. The tricuspid valve was undoubtedly dilated and incompetent. We may wonder about tricuspid stenosis, but cannot make this as a positive diagnosis. In the treatment of the congestive failure, total thyroidectomy was given a trial. As we read this protocol, we can hardly believe that this procedure accomplished a great deal for the patient, unless it were in prolonging a rather miserable life. I believe we shall find that a full ablation of the gland was not done and that regeneration of functional tissue took place. The

alternate to this may be that aberrant thyroid tissue was present and subsequently hypertrophied. A large part of the parathyroid tissue must have been removed at operation, resulting in a persistent hypoparathyroidism; we may find a scarred portion of one gland remaining. All the visceral organs must have shown an extreme degree of chronic passive congestion from the years of heart failure. We may wonder about cardiac cirrhosis, but chronic ascites toward the end was hardly significant enough to warrant this diagnosis, and the liver remained enlarged. We have evidence for at least one old embolic scar in the left kidney, and similar areas of infarction may have been found in the other organs. I am left wondering about the kidneys. In the later entries, further information regarding nonprotein nitrogen and urinary findings is not given. We know that there had been a urinary infection. Undoubtedly, the kidneys, like the liver, showed an extreme degree of chronic passive congestion, and it is possible that they showed a superimposed chronic pyelonephritis. There may well also have been a focal nephritis.

#### CLINICAL DIAGNOSES

Rheumatic heart disease, with mitral stenosis and regurgitation.  
Tricuspid regurgitation?  
Hypothyroidism.  
Hypoparathyroidism?  
Auricular fibrillation.

#### DR. CLARK'S DIAGNOSES

Rheumatic heart disease: mitral stenosis; aortic and tricuspid involvement (?).  
Cardiac cirrhosis?  
Chronic passive congestion.  
Hypoparathyroidism.  
Regeneration of thyroid gland.  
Pyelonephritis?

#### ANATOMICAL DIAGNOSES

Rheumatic heart disease: mitral stenosis and regurgitation; aortic stenosis, slight; tricuspid regurgitation; pulmonary endocarditis, slight; adhesive pericarditis.  
Chronic passive congestion.  
Cardiac cirrhosis of the liver.  
Hydrothorax, bilateral, slight.  
Ascites.  
Hemorrhagic enterocolitis, acute.  
Partial regeneration and hyperplasia of thyroid gland.  
Partial removal of thyroid and parathyroid glands.

## PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: The essential pathologic lesion in this case was, of course, rheumatic heart disease. As Dr. Clark predicted, there was a high grade of mitral stenosis, and, as he suspected but could not prove, the aortic and tricuspid valves were also involved. There was enough interadherence of the aortic cusp to have produced a slight but definite stenosis, and the chordae of the tricuspid valve were so shortened that there must have been regurgitation. A minimal scarring, without functional deformity, was also noted on the pulmonary valve. Further evidence of a pancarditis was an almost complete fibrous obliteration of the pericardial cavity. Neither in the valves nor in the myocardium could we find any evidence of acute rheumatic infection.

Another suspicion of Dr. Clark's was likewise confirmed. The liver was small, and its surface very finely pebbled; it cut with definitely increased resistance. On microscopic examination, distinct fibrosis of the centers of the lobules was apparent, in addition to the evidence of severe passive congestion. So that the diagnosis of cardiac cirrhosis was confirmed.

The lungs showed little except chronic passive congestion, and the terminal episode proved to have been a diffuse hemorrhagic enterocolitis, which was entirely unexpected. The kidneys were surprisingly normal. They were of course, slightly swollen and congested, but there was no evidence of pyelonephritis, and we did not find any scar of a healed infarct. As Dr. Clark guessed, the thyroidectomy had not been total. A nodule that weighed between 2 and 3 gm. and showed on microscopic examination intense hyperplasia had regenerated. In a search for parathyroid glands, a small fragment of accessory thyroid tissue was found, which was likewise hyperplastic. No parathyroid gland could be identified.

## CASE 27522

## PRESENTATION OF CASE

A fifty-one-year-old Italian laborer was transferred to the Emergency Ward from another hospital because of coma and increasing neurologic signs of thirty-six hours' duration.

Five weeks before admission, the patient became flushed, had chills, began to cough, and complained of pain in the left lower chest. He remained in bed for three days, but did not improve and entered a local hospital, where examination showed crackling rales over the upper left chest, with dullness to flatness below the level

of the left fourth rib. There was marked bronchovesicular breathing in the right chest. An x-ray film showed consolidation in the left lower lobe of the lung. The head and abdomen were normal.

The patient was treated with sulfathiazole, but responded poorly. Subsequent x-ray films showed persistent consolidation in the left base, and an apparent left interlobar mass, which became progressively more prominent. Several chest taps failed to reveal fluid or pus. The temperature spiked between 101 and 105°F. (rectal) for two and a half weeks. Following a four-day course of sulfapyridine, the temperature returned to normal, and there was general improvement in the patient's condition.

Five weeks after onset of the illness, while still in the local hospital, the patient suddenly became apathetic, listless and unresponsive. He developed sphincter incontinence, and in the course of thirty-six hours lapsed into deep coma.

The family history was noncontributory. The patient was a chronic alcoholic.

Physical examination showed a comatose, apparently moribund man who was breathing stertorously but regularly. There was no cyanosis. A leathery rub was heard in the left axilla, and there were scattered rales in the left base. Dullness was evident posteriorly on the left at the level of the fifth and sixth ribs, medial to the scapula. The liver edge seemed firm and smooth and was two fingerbreadths beneath the costal margin. The pupils were round but unequal, and reacted to light. The fundi showed full retinal veins, with initial blurring of the disks. There was a suggestive left central facial weakness. The head was held tilted and rotated to the left, with marked rigidity of the neck. All extremities were hyper-tonic, the right arm more than the left. The tendon reflexes were exaggerated bilaterally although more markedly so on the right. The abdominal reflexes were absent, and the Babinski reflex was positive on both sides.

The heart sounds were rapid and distant. The pulse was 110, the temperature 106°F., and the respirations 40.

Examination of the blood showed a red-cell count of 3,050,000 with a hemoglobin of 50 per cent, and a white-cell count of 21,600 with 93 per cent polymorphonuclears. The urine showed a specific gravity of 1.014, with a +++ test for albumin, no sugar, and only occasional white cells in the sediment. The nonprotein nitrogen of the blood serum was 20 mg. per 100 cc.

A lumbar puncture gave 6 cc. of turbid, later blood-tinged fluid, the pressure falling from 155

to 125 mm. of water. The respiratory and pulse oscillations were normal. The fluid showed a white-cell count of 4670, with polymorphonuclear leukocytes predominating. Gram-positive cocci in pairs and chains appeared on smear. Puncture of the left chest in the fifth interspace, 10 cm. lateral to the spinous process, yielded 45 cc. of sanguinopurulent fluid.

A roentgenogram of the chest showed homogeneous density obliterating the left side of the diaphragm, rising to the fourth rib posteriorly in a thin band. The heart was not displaced. A roentgenogram of the skull was normal.

The patient was continued on sulfapyridine, and a blood level of 13 mg. per 100 cc. was obtained. He was given repeated intravenous fluids and oxygen therapy.

Death occurred on the third hospital day, five and a half weeks after onset of the illness.

#### DIFFERENTIAL DIAGNOSIS

DR. AUGUSTUS S. ROSE: The cause of death in this case was clearly an intracranial infectious process. Meningitis was definitely established, as was the intrapleural infection from which the meningitis ultimately arose. The neurologic problem is therefore confined to the question of the co-existence of a brain abscess.

The terminal illness began with fever, chills, cough and pain in the chest, and physical and x-ray examinations confirmed the suspicion of lobar pneumonia. The consolidation, however, did not clear, and for a time, the patient responded poorly to clinical therapy. At this time, empyema, which was unquestionably present, was suspected, but fluid was not obtained by chest tap. Two and a half weeks later, while apparently convalescing, the patient suddenly became semicomatose, lost sphincter control and grew progressively worse until death three days later.

We are not told of the symptoms that he must have had during the two weeks between the two acute phases of his illness. But thirty-six hours after the onset of coma, physical examination and, indeed, a chest tap revealed the persistence of the empyema. Neurologic examination showed a stiff neck, unequal pupils, distended retinal veins, with a question of early papilledema, a suggestive left central facial weakness, unequal hyperactive reflexes and bilaterally positive Babinski signs. Lumbar puncture showed turbid, blood-tinged spinal fluid, with a white-cell count of 4600 cells and a normal pressure (155 mm. of water). A smear of the fluid showed gram-positive cocci in pairs and chains. The sugar determination would be of interest, but is unnecessary.

On the basis of these facts, we can say the patient had empyema of the left pleura and pneumococcal meningitis. However, does pneumococcal meningitis explain the total picture? Was there a brain abscess that ruptured into a ventricle?

Pneumococcal meningitis may be one of the most fulminating of meningeal infections. Not infrequently, it is ushered in by a convulsion and coma, and if the infection is untreated, death may follow in a day or two. More commonly, however, headache, chills and apathy precede the more dramatic symptoms by some hours. Neurologic signs, as in this case, may also appear in meningitis, because of degenerative changes in the cells of the cortex and brain stem, secondary to the overlying exudate and infection. There is room for doubt whether such widespread damage would occur in thirty-six hours as to produce the signs exhibited by this patient when the spinal-fluid pressure was normal. The pressure is almost universally elevated in severe meningitis. The absence of increased pressure in this case requires explanation. It is also unusual to find blood-tinged spinal fluid in uncomplicated meningitis.

These objections to meningitis (sudden onset, many neurologic signs, normal spinal-fluid pressure and blood-tinged spinal fluid) can be met by the diagnosis of one or more metastatic brain abscesses, with rupture of one into a lateral ventricle. It is possible that a bacteremia occurred during the first or second week of the illness, while the temperature was spiking. The advancing pulmonary infection could have overshadowed symptoms referable to the head. If the cerebral lesion had been located near the ventricular wall, dramatic neurologic signs would not necessarily have developed. Furthermore, it is a frequent clinical observation that a brain abscess may attain considerable size before the development of increased intracranial pressure. The rupture of an abscess into a ventricle almost invariably changes a relatively benign localized infection into a sudden, overwhelmingly malignant one.

#### CLINICAL DIAGNOSES

Pneumonia.  
Empyema.  
Brain abscess.  
Meningitis.

#### DR. ROSE'S DIAGNOSES

Empyema, left pleura.  
Pneumococcal meningitis.  
Brain abscess, ruptured.

conserved. These standards are necessarily high. It is possible that they should be still higher. In any event, the average physician is not familiar with them. He should be, for to him may fall the task of preliminary examination of applicants for one or another branch of the Army or Navy, and on him devolves the task of preventing or correcting, if possible, the defects in selectees or such applicants that disqualify for full military service. In this respect, two articles in this issue of the *Journal*, which deal with the cardiovascular standards for the United States Army and the general physical standards for its aviation cadets, are of particular interest. These standards should even be attained in civilian life, and they could be if the average physician were conversant with them. A better and stronger nation would result—come what may.

"Health is the second blessing that we mortals are capable of, a blessing that money cannot buy"—but wisdom and knowledge may.

## MEDICAL EPONYM

### LOEFFLER'S MEDIUM

The description of the culture medium that still bears his name occurs on page 461 of the monograph by Friedrich August Johann Loeffler (1852-1915), of Berlin, "Untersuchungen über die Bedeutung der Mikroorganismen für die Entstehung der Diphtherie beim Menschen, bei der Taube und beim Kalbe [Studies in the Significance of Micro-organisms in the Occurrence of Diphtheria in Man, in the Pigeon and in the Calf]," which was published in *Mittheilungen aus dem kaiserlichen Gesundheitsamte* (2: 421-499, 1884). A portion of the translation follows:

When the bacilli were sown on the above-mentioned coagulated mixture of 3 parts of calves' or sheep's blood serum and 1 part of neutralized veal broth to which had been added peptone, 1 per cent, glucose, 1 per cent, and sodium chloride, 0.5 per cent, the organisms grew so luxuriantly that at the end of two days there was a whitish coat nearly 1 mm. thick over the surface of the serum, and single colonies had attained an average size of 0.5 cm. In all subsequent trials, therefore, this broth-peptone-glucose serum alone was used as a nutritive base.

## MASSACHUSETTS MEDICAL SOCIETY

### SECTION OF OBSTETRICS AND GYNECOLOGY\*

#### FATAL SUPPURATIVE UTERINE INFECTION AND PERITONITIS FOLLOWING SELF-INDUCED ABORTION

A twenty-six-year-old unmarried woman was seen at home by her private physician and immediately sent into the hospital. She had passed a fetus five hours previously, and was thought to have been about three months pregnant. Since this was a medicolegal case, the past history was not complete. The patient was reported to have had an illegitimate pregnancy at term three years before the present episode. She was of subnormal mentality, and there was no history of illnesses of any sort.

On entry to the hospital, she had a foul lochia, a subnormal temperature, a pulse of 100 and respirations of 32. Under spinal anesthesia, the patient was curetted, and the uterus swabbed out with iodine. She remained in the hospital only three days and left against advice. During the hospital stay, the temperature did not go above normal.

Two and a half weeks later, she was referred to another hospital by another physician because of acute generalized abdominal pain and vomiting of three days' duration. Examination showed the abdomen to be generally tender, spastic and distended. There was no record of the temperature and pulse, but both were presumably elevated. Blood culture showed a staphylococcus. Sulfanilamide therapy, which had been started, was stopped after the report of the blood culture. The patient died two weeks after entry. Autopsy revealed a septic uterus and an acute suppurative generalized peritonitis.

*Comment.* There is little question that this was a self-induced abortion. This patient was described as being mentally subnormal. Pregnancy in this class of person is a great social problem; abortion is not frequent—much oftener these pregnancies go to term and complicate the social and economic problem for the state.

Although the patient herself was responsible for this death, the treatment that she received on entering the hospital is open to criticism. Conservatism in the handling of all septic abortions

\*A series of selected case histories by members of the section have been published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the section. Letters should be addressed to Dr. Raymond S. Titus, Secretary, 330 Dartmouth Street, Boston.

should be followed, this means leaving the uterus absolutely alone, except in the face of hemorrhage. In this case, the curettage was done not because of hemorrhage but because the patient was known to have aborted and still had a foul smelling lochia. Since no temperature reaction followed this intrauterine manipulation, it may well be that the curettage did no appreciable harm, and it is barely possible that had this patient stayed in the hospital, the fatal outcome might have been prevented. In view of the subsequent history and the autopsy findings, sepsis was present in spite of the normal temperature when the patient went home. The diagnosis of peritonitis was so apparent when she entered the second hospital that only conservative treatment was applicable. It would be very helpful to the medical profession if the medical examiners were adamant in performing autopsies in all cases of maternal death that come under their jurisdiction.

If hemorrhage is a complication of septic abortion, it must be controlled, and the retained products, whose presence in the uterus is the cause of the hemorrhage, must be removed. The removal of such products should be done with the greatest care, preferably with the finger and not the curet, and the uterus should be picked to control further bleeding. Acute hemorrhage should be treated by transfusion, and in all septic abortions cultures from the uterus and blood stream should be taken and intelligent chemotherapy instituted. But in the absence of hemorrhage, the uterus should be left alone.

## DEATHS

**DUFFY**—JAMES J. DUFFY, MD, of New York City, died recently. He was in his fifth year.

Born in Webster, Massachusetts, Dr. Duffy received his degree from Harvard Medical School in 1919. He was a former member of the Massachusetts Medical Society.

**FLEMING**—PETER J. FLEMING, MD of Jamaica Plain, died December 15. He was in his sixty-seventh year.

Dr. Fleming received his degree from the University of Western Ontario Medical School in 1902. He was a member of the Massachusetts Medical Society and the American Medical Association.

His widow survives him.

**MANNING**—ARTHUR F. MANNING, MD, of Waltham, died December 12. He was in his fortieth year.

Dr. Manning received his degree from Harvard Medical School in 1928. He was a member of the Massachusetts Medical Society and the American Medical Association.

His widow survives him.

**MARTIN**—ARCHIBALD H. MARTIN, MD, of Lynn, died December 13. He was in his seventieth year.

Born in Manchester, New Hampshire, Dr. Martin re-

ceived his degree from the College of Physicians and Surgeons, Boston in 1896. He was a fellow of the Massachusetts Medical Society and the American Medical Association.

He is survived by his widow, a daughter and a son.

## DEFENSE ACTIVITIES

### CIVILIAN DEFENSE

#### TRAINING OF VOLUNTEER NURSES' AIDES

The national emergency has brought about a shortage of nurses in hospitals, clinics, public-health and field nursing agencies. To relieve this situation, which is likely to grow more acute with the expansion of military establishments and of plans for civilian defense, the American Red Cross and the Office of Civilian Defense have jointly undertaken a project to train volunteer nurses' aides. With such assistance graduate nurses may extend their services to many more persons. The volunteer aides will work under supervision of a nurse and are being trained for certain nontechnical tasks in order that graduate nurses may be released for the highly technical duties to which alone they are qualified to perform.

The local chief of emergency medical service and the local office of civilian defense in communities where the training program is undertaken have definite responsibilities listed as follows by the national headquarters of the Office of Civilian Defense:

(1) To assist the local Red Cross chapter and the Civilian Defense Volunteer Office in recruiting and enrolling desirable applicants for training.

(2) To assist local chapters to conclude arrangements with appropriate general hospitals to serve as training centers.

(3) To assist the local Red Cross chapter in organizing and maintaining a placement service so that volunteer nurses' aides may continue to serve and to accumulate experience.

(4) To reassign volunteer nurses' aides to emergency duty if the need should arise.

The American Red Cross, in collaboration with the Medical Division of the Office of Civilian Defense, has revised its standard course of instruction for volunteer nurses' aides with reference to needs that may develop during the period of the national emergency. The standard course was instituted in July, 1940, an outgrowth of volunteer services that have been sponsored by the Red Cross since World War I. The first half of the course, consisting of lectures and demonstrations, is given in a Red Cross chapter house or some other suitable place. The second half is given in a hospital selected by the American Red Cross and the Office of Civilian Defense as a training center under strict supervision.

Nurses' aides are to work under supervision of a nurse at all times, never independently, the instructions point out. Moreover, they must agree to serve without remuneration and in time of national peril must be prepared to serve whenever and for as long a period as needed. Authorized duties for the nurses' aides have been outlined in the Red Cross publication, *Chapter Organization and Administration of Red Cross Volunteer Nurses Aide Corps*. These duties are of course subject to approval of individual institutions. In hospitals they may, among other activities, make beds, take care of personal belong-

ings of patients, take care of rubber goods, clean dressing trays, take care of linen closets, feed helpless patients, take patients to and from treatment rooms, help with admission and discharge of patients and care for ambulatory patients. In dispensaries and clinics the aides may serve as interpreters in foreign languages, interpret clinic rules and instructions to patients, help weigh and measure, undress and dress children, assist in taking physicians' notes, help with inventories, clean and put away instruments and help put rooms in order after clinics. In community health agencies the aides may perform whatever nursing duties are approved by the organization for which they work, provided these duties are performed under the direct supervision of a nurse.

## MISCELLANY

### HUNTINGTON MEMORIAL HOSPITAL

Harvard University and the Massachusetts General Hospital have recently announced the conclusion of an agreement by which the main phases of the work in cancer treatment and research now being carried on by the Collis P. Huntington Memorial Hospital will be transferred to the Massachusetts General Hospital. The change will become effective as early in 1942 as possible.

"This step is being taken," the statement said, "in accordance with a long-held belief of both the University and the Massachusetts General Hospital that the care and treatment of medical specialties can be more efficiently handled as part of a large institution of general scope than in smaller individual units. Both the hospitals concerned have been major factors in the study and treatment of cancer in the New England area for many years; and it is confidently believed that the combination of their facilities will not only provide an improved service for patients suffering from malignant disease, but will also render such service more economically to the general community.

"Under the new arrangement, there will be transferred to the Massachusetts General Hospital the inpatient and outpatient services now available at the Huntington Memorial Hospital. By extension of its outpatient service, the Massachusetts General Hospital can readily accommodate all patients who have heretofore been using the Huntington Hospital; during the last year the latter cared for 14,000 outpatient visits. The Massachusetts General Hospital also has ample space in which to set up additional beds to equal the present complement at the Huntington Hospital; hence there will be no reduction in the number of beds available for the care of cancer patients in the community as a result of the change.

"The Laboratory and research work now carried on by the Harvard Cancer Commission through employment of certain funds of Harvard University will continue under supervision of that commission. Research activities under the direction of Dr. Joseph C. Aub will be carried on at the Massachusetts General Hospital in connection with the large and well-organized tumor clinic which that hospital has been operating for many years. The remainder of the varied research work of the Harvard Cancer Commission will be continued in conjunction with the Harvard Medical School.

"The equipment of the Massachusetts General Hospital, including its modern 1,000,000-volt x-ray machine, will be available to all patients, and the Harvard supply of radium, heretofore used at the Huntington Hospital, will be transferred to the Massachusetts General Hospital."

## RÉSUMÉ OF COMMUNICABLE DISEASES IN MASSACHUSETTS FOR OCTOBER, 1941

DISEASES	OCTOBER 1941	OCTOBER 1940	FIVE YEAR AVERAGE*
Anterior poliomyelitis	45	7	13
Chicken pox	571	491	367
Diphtheria	9	20	16
Dog bite	902	845	778
Dysentery, bacillary	43	21	43
German measles	35	26	28
Gonorrhea	351	374	455
Measles	373	619	258
Meningitis, meningococcal	10	5	5
Meningitis, other forms	2	—	—
Mumps	335	199	179
Paratyphoid infections	6	3	2
Pneumonia, lobar	192	219	229
Scarlet fever	467	266	291
Syphilis	450	394	430
Tuberculosis, pulmonary	342	223	243
Tuberculosis, other forms	33	30	30
Typhoid fever	11	6	6
Undulant fever	6	3	5
Whooping cough	555	645	491

\*Based on figures for preceding five years

### GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Actinomycosis was reported from Boston, 1; Reading, 1; total, 2.

Anterior poliomyelitis was reported from: Acushnet, 3; Adams, 1; Andover, 1; Boston, 4; Bourne, 1; Brockton, 2; Cambridge, 1; Carver, 1; Chelsea, 1; Danvers, 1; Dedham, 1; Falmouth, 1; Fall River, 1; Lowell, 1; Lynn, 4; Malden, 1; Merrimac, 1; New Bedford, 2; North Attleboro, 1; Norfolk, 1; Pittsfield, 3; Saugus, 1; Southboro, 1; Springfield, 1; Taunton, 2; Wakefield, 1; Walpole, 1; Ware, 2; Wellesley, 1; West Bridgewater, 1; total, 45.

Anthrax was reported from: Holyoke, 1; Springfield, 1; total, 2.

Diphtheria was reported from: Boston, 1; Bourne, 1; Fall River, 6; Worcester, 1; total, 9.

Dysentery, bacillary, was reported from: Adams, 1; Arlington, 1; Boston, 3; Dracut, 2; Ipswich, 5; Lawrence, 1; Lowell, 1; Melrose, 8; Springfield, 1; Worcester, 20; total, 43.

Infectious encephalitis was reported from: Lynn, 1; Springfield, 1; total, 2.

Meningitis, meningococcal, was reported from: Boston, 1; Brockton, 1; Ipswich, 1; Fort Devens, 1; New Bedford, 1; Quincy, 1; Randolph, 1; Waltham, 1; Woburn, 2; total, 10.

Meningitis, other forms, was reported from: Brockton, 1; Taunton, 1; total, 2.

Paratyphoid infections were reported from: Boston, 2; Everett, 1; Fort Devens, 1; Lynn, 1; Malden, 1; total, 6.

Septic sore throat was reported from: Boston, 2; Fall River, 1; Hingham, 1; Medford, 2; New Braintree, 1; Salisbury, 1; Waltham, 1; Weymouth, 1; Williamstown, 1; total, 11.

Tetanus was reported from: Boston, 1; total, 1.

Trachoma was reported from: Boston, 1; Dedham, 1; Lynn, 1; total, 3.

Trichinosis was reported from: Attleboro, 1; Boston, 1; total, 2.

Typhoid fever was reported from: Boston, 3; Brockton, 1; Cambridge, 1; Fall River, 1; Fitchburg, 1; Norwood, 1; Springfield, 1; Westwood, 1; Worcester, 1; total, 11.

Undulant fever was reported from: Great Barrington, 1; Mendon, 1; North Adams, 1; Worcester, 3; total, 6.

Anterior poliomyelitis continued at a level above the usual seasonal incidence of nonepidemic years.

Chicken pox, dog bite and mumps showed record high incidences, this being the second consecutive month for dog bite and the fourth for mumps.

Scarlet fever had the highest prevalence for October since 1935.

German measles, measles, meningococcal meningitis, paratyphoid infections, pulmonary tuberculosis, typhoid fever, and whooping cough were reported above the five year averages.

Diphtheria and lobar pneumonia were reported below the five year averages.

The incidences of bacillary dysentery and undulant fever were not remarkable.

## NOTE

The election of Dr George R Minot, professor of medicine at Harvard Medical School, as president of the Inter State Postgraduate Medical Association of North America was recently announced.

## CORRESPONDENCE

### HEALTH OF THE WORKER AND HIS FAMILY

To the Editor: I noted with great interest and satisfaction the inclusion in the December 11 issue of the *Journal* of an article by Mr Bloomfield entitled "The Private Physician's Opportunity in Industrial Medicine" and another by Dr Pinto and Mr Bowditch entitled "Industrial Medicine." Also, your board saw fit to devote an editorial to this subject.

We have been frequently reminded that the present war is different from any other in which we have ever engaged and that there are two fronts that defended by the armed forces and that supported by civilians, the most important of whom are those engaged in defense industries. There is a degree of satisfaction in this latter point, since every person has a definite sense of playing his part in winning the war and defending the freedoms for which we are fighting. Today, the boy who is found physically unfit for service, but who is by no means an invalid, can hold his head high with the sense that he has a duty and a service to perform that is second only to the man at the front. This is also true of older people and of women, and it is going to require the full measure of effort of a determined people, physically fit and with a high war morale, to win out against our powerful and treacherous foes.

Industrial hygiene is not a new field. Those concerned with this work, however, have quite generally been interested only in those diseases or injuries that arise because of certain inherent conditions within a particular industry. We are reminded by Mr Bloomfield's article that there is enormous waste of life and efficiency resulting from nonindustrial illness among workers. It is estimated that of the 400,000,000 man-days a year lost because of disabilities, only 5 or 10 per cent can be classified as due to specific industrial hazards. The major problem has to do, obviously, with the various forms of illness, such as respiratory infections, gastrointestinal disease and the like, that occur in all people but show in excess, oftentimes, among industrial workers. It is a familiar fact that disease prevalence varies inversely with income when this is below a certain level. We know that women in industry suffer from an excess of absenteeism six times that of men. If we are really going to make a contribution to the war effort, the greatest opportunity lies in the field of reducing the common illnesses of man.

I am not, in this, belittling the value of setting up the necessary safeguards against chemical poisonings, dust hazards, physical injury and other specific industrial diseases, but I am saying that we must change the general philosophy that has prevailed and look realistically at the relative values of our efforts in this field and that employers, employees, industrial physicians, private physicians, industrial nurses and all the rest of us must adopt a new point of view. There are the same possibilities of reducing sickness among the industrial workers who congregate together daily as there are in prevailing diseases in the general community. The field is as broad as the whole public health program.

To study ways and means of assisting and furthering a complete industrial hygiene program, the Health Division of the Massachusetts Committee on Public Safety has created the Committee on Occupational Hygiene, which comprises representatives from the Massachusetts Medical Society, employers, employees, industrial nurses, insurance companies, the health-education group and the Massachusetts Division of Industrial Hygiene. It is hoped that they may bring forth a program that will be constructive and helpful to all concerned in reducing the wastage of manpower resulting from all forms of preventable diseases among the laboring classes.

CURTIS M. HILLIARD, *Director*

Health Division Massachusetts Committee on Public Safety  
18 Fremont Street  
Boston

## REPORTS OF MEETINGS

### PLYMOUTH DISTRICT MEDICAL SOCIETY

A regular meeting of the Plymouth District Medical Society was held November 13 at the Plymouth County Hospital at 11 15 am. The meeting was called to order by the president Dr G A Moore. The minutes of the previous meeting were read by the secretary, Dr R C McLeod. Mention was made of the death of Dr H H Burns, of Plymouth, in May, 1941.

Dr Bradford Peirce presented a program of films and slides of tuberculous patients treated at the South Hanover Hospital by modern methods, including lobectomy, pneumonectomy, thoracoplasty and pneumolysis. These were illustrated by several cases with recovery. Dr Moore made comment on the vastly improved death rate in tuberculosis in the past thirty years, attributing at least part of the improvement to surgical intervention, and touched lightly on lobectomy and pneumonectomy, which are reserved for well selected cases, he added that, as a rule, the operative results are excellent.

The main speaker was Dr J C McCann, of Worcester, chairman of the Committee on Medical Care Costs Insurance. He gave an outstanding and vigorous plea for co operation by all members of the society, which was well received.

EDWARD S. PERRY, M.D., *Reporter*

### MIDDLESEX SOUTH DISTRICT MEDICAL SOCIETY

Dr James C. McCann of Worcester, chairman of the special committee concerned with prepayment medical care costs insurance, spoke at a meeting of the Middlesex South District Medical Society on December 10.

The members of the society passed a resolution, made

by Dr. Charles E. Mongan, that supported the work of Dr. McCann and his committee. It was requested that this fact be published in the *New England Journal of Medicine*.

ALEXANDER A. LEVI, *Secretary*

## BOOK REVIEWS

*The Care of the Aged (Geriatrics)*. By Malford W. Thewlis, M.D. Third edition, entirely rewritten. 8°, cloth, 579 pp., with 50 illustrations. St. Louis: The C. V. Mosby Company, 1941. \$6.00.

The author's long interest in old people is shown by the fact that he has rewritten this book, which first appeared in 1919. It consists of thirty-eight chapters grouped in five sections, and it claims to be "still the only recent book dealing with the medical care of the aged."

The first section, "General Considerations," sketches the value of old-age hygiene, the prevention of premature senility, prolongation of life, work for the aged, hobbies, economic problems and medicolegal relations. Many interesting observations are found, but in general the reviewer believes that the discussion suffers both from incompleteness and from repetition. Exercise is disposed of in five lines. Recreation is given one paragraph, as follows: "Recreation is an important factor. The aged brain becomes fatigued easily; a sophisticated play or film, which causes mental strain should be avoided. The senescent mind reacts well to something lively and humorous." Heredity is discussed in several places. Furthermore, it is not always clear whether the author is thinking of the normal person of sixty, seventy or ninety, of the institutionalized pauper or of the senile dement.

The second section, "Miscellaneous Medical Problems," includes chapters on nutrition, nursing and therapeutics. The chapters on anatomic and pathologic changes in old age suffer seriously on comparison with the scholarly reports in Cowdry's *Problems of Ageing*. The third and fourth sections deal with infectious and noninfectious diseases (the latter are defined as allergy, alcoholism and focal infections).

In the fifth section, "Pathologic Conditions in Old Age," there are subtitles for practically every condition dealt with in standard textbooks of medicine and surgery, with numerous references to medical literature. Statements concerning the changes imposed by age on disease and on its treatment are often given as impressions and as recollections of individual cases drawn from a rich experience. They show good clinical judgment for the most part. Careful reading and rereading, however, leaves one wishing that there were more evidence of critical study and correlation.

The book cannot be highly recommended, since it is not a satisfactory guide to the care of the aged. On the road to geriatrics, it is "a landmark, not a guide post."

*Natural Resistance and Clinical Medicine*. By David Perla, M.D. and Jessie Marmorston, M.D. 4°, cloth, with 1344 pp. and 44 tables. Boston: Little, Brown and Company, 1941. \$10.00.

This is a curious book. Its authors for some time have evidently been interested in what resistance to disease may be, and here, as they say, they have attempted to put down in print an analysis of many of the factors that are believed to determine or modify natural or acquired susceptibility to infection.

The task of putting together such a book is enormous. The authors quote more than five thousand references to

current literature in the forty-six chapters that make the volume. Almost every conceivable phase of resistance to disease is discussed, from the prevention and treatment of surgical shock to the role of copper, iron or manganese to resistance, or from the effect of psychic factors to the effect of age and sex, of endocrine glands or of vitamins.

This is the kind of medical text that one would expect to find in a library—useful for reference or to encourage browsing. It can have very little general appeal to students or practicing doctors. It deserves praise, however, as being an honest effort toward gathering a large conglomeration of literature and crystallizing therefrom a number of stimulating ideas.

New England readers may be interested to know that this is the first large American medical publication to be printed by Little, Brown and Company of Boston. For a book so large, its physical characteristics are handsome. It weighs no more than it has to for its size; the typography is admirable; the indexing is adequate; the illustrations and tables are clear. The appearance of the book, therefore, carries on the fine tradition of expert book making upheld for so many years by its publishers.

*The Principles and Practice of Ophthalmic Surgery*. Edmund B. Spaeth, M.D. Second edition, thoroughly revised. 8°, cloth, with 1149 illustrations and 6 colored plates. Philadelphia: Lea and Febiger, 1941. \$10.00.

Effective surgery is consummated only when a comprehensive diagnosis is combined with surgical skill and ingenuity. In the field of ophthalmology, the internist, neurologist and the ophthalmologist find a common diagnostic meeting ground. The author of this book wisely recognizes the importance of diagnosis, and he incorporates diagnostic considerations as the prerequisite for the choice and application of surgical therapy. The text carries authors' index, as well as a general index.

Lucid writing, a wealth of well-chosen illustrations freely given credits to authorities in their respective fields make this book the collective voice of modern work everywhere, and an indispensable guide for every current practitioner of eye surgery. The twenty-six chapters of the book deal with anesthesia, reconstructive plastic surgery of the eyelids and socket, surgery of the lacrimal apparatus, surgery of the ocular muscles, cataract surgery, glaucoma surgery, reattachment of a separated retina, extraction of intraocular foreign bodies and treatment of radium and surgery of neoplasms of the eye and adnexa.

*A Textbook of Ophthalmology*. By Sanford R. Gifford, M.D. Second edition, revised. 8°, cloth, 470 pp., with 255 illustrations and 14 colored plates. Philadelphia: W. B. Saunders Company, 1941. \$4.00.

The second edition of Gifford's excellent work corrects the typographic errors of the first edition, and is reprinted with many informative illustrations in black and white and in color. The author has rewritten portions of the book to cover advances in knowledge that have taken place since the publication of the first edition, notably in chemotherapy as applied to ophthalmology, and in the ophthalmic manifestations of general diseases.

The practitioner and the medical student will find here concise, interesting and dependable information to guide them in understanding how to deal with the ophthalmic problems that arise in practice.
